## TABLE OF CONTENTS

ADAMS, P. B., S. RALSTON, AND T. E. LAIDIG.
1993. Occurrence of an exceptional catch of pelagic juvenile lingcod (*Ophiodon elongatus*) off Point Reyes, California. Fish. Oceanogr. 2(2):97–100. . . . . . . . . . . 9301

AINLEY, D. G., W. J. SYDEMAN, R. H. PARRISH, AND W. H. LENARZ.
1993. Oceanic factors influencing distribution of young rockfish (*Sebastes*) in central California: a predator's perspective. Calif. Coop. Oceanic Fish. Inv. Rep. 34:133–139. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9302

ALAUDDIN, M., D. SQUIRES, AND C. TISDELL.
1993. Divergency between average and frontier production technologies: an empirical investigation for Bangladesh. Appl. Econ. 25:379–388. . . . . . . . . . . . . . 9303

ATKINSON, S., W. G. GILMARTIN, AND B. L. LASLEY.
1993. Testosterone response to a gonadotrophin-releasing hormone agonist in Hawaiian monk seals (*Monachus schauinslandi*). J. Reprod. Fert. 97:35–38. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9304

BAGARINAO, T., AND R. D. VETTER.
1993. Sulphide tolerance and adaptation in the California killifish, *Fundulus parvipinnus*, a salt marsh resident. J. Fish. Biol. 42:729–748.. . . . . . . . . . . . . . . . . 9305

BAILEY, K. M., R. D. BRODEUR, N. MERATI, AND M. M. YOKLAVICH.
1993. Predation on walleye pollock (*Theragra chalcogramma*) eggs and yolk-sac larvae by pelagic crustacean invertebrates in the western Gulf of Alaska. Fish. Oceanogr. 2(1):30–39. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9306

BALAZS, G. H.
1993. Annotated list of shark attacks in the Hawaiian Islands, 1779–1993. Appendix A. *In* J. Borg, Tigers of the sea: Hawaii's deadly sharks, p. 63–83. Mutual Publishing, Honolulu, Hawaii.. . . . . . . . . . . . . . . . . . . . . . . . . . 9307

BALAZS, G. H., R. FUJIOKA, AND C. FUJIOKA.
1993. Marine turtle faeces on Hawaiian beaches. Mar. Pollut. Bull. 26:392–394. . . . . . 9308

BARLOW, J., L. FLEISCHER, K. A. FORNEY, O. MARAVILLA-CHAVEZ.
1993. An experimental aerial survey for vaquita (*Phocoena sinus*) in the northern Gulf of California, Mexico. Mar. Mamm. Sci. 9(1):89–94. . . . . . . . . . . . 9309

BARTOO, N., AND D. HOLTS.
1993. Estimated drift gillnet selectivity for albacore *Thunnus alalunga*. Fish. Bull., U.S. 91:371–378. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9310

## TABLE OF CONTENTS (CONTINUED)

BARTOO, N., D. HOLTS, AND C. BROWN.
1993. Evidence of interactions between high seas driftnet fisheries and the North American troll fishery for albacore. Int. North Pac. Fish. Comm. Bull. 53:367–380 . . . . . . . . . 9311

BENCE, J. R., A. GORDOA, AND J. E. HIGHTOWER.
1993. The influence of age-selective surveys on the reliability of stock synthesis assessments. Can. J. Fish. Aquat. Sci. 50(4):827–840. . . . . . . . . 9312

BIGELOW, K. A., AND K. C. LANDGRAF.
1993. Hatch dates and growth of *Ommastrephes bartramii* paralarvae from Hawaiian waters as determined from statolith analysis. *In* T. Okutani, R. K. O'Dor, and T. Kubodera (eds.), Recent advances in fisheries biology, p. 15–24. Tokai University Press, Tokyo. . . . . . . . . 9313

BOEHLERT, G. W.
1993. Fisheries and marine resources of Hawaii and the U.S.-associated Pacific islands: an introduction. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):3–6. . . . . . . . . 9314

BOEHLERT, G. W., AND B. C. MUNDY.
1993. Ichthyoplankton assemblages at seamounts and oceanic islands. Bull. Mar. Sci. 53(2):336–361. . . . . . . . . 9315

BOGGS, C. H.
1993. Methods for analyzing interactions of limited-range fisheries: Hawaii's pelagic fisheries. *In* R. S. Shomura, J. Majkowski, and S. Langi (eds.), Proceedings of the first FAO expert consultation on interactions of Pacific tuna fisheries, Noumea, New Caledonia. Volume 1: summary report and papers on interaction, p. 74–91. FAO Fish. Tech. Pap. 336/1. . . . . . . . . 9316

BOGGS, C. H., AND R. Y. ITO.
1993. Hawaii's pelagic fisheries. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):69–82. . . . . . . . . 9317

BOGGS, C. H., AND B. S. KIKKAWA.
1993. The development and decline of Hawaii's skipjack tuna fishery. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):61–68. . . . . . . . . 9318

BRILL, R. W., AND D. B. HOLTS.
1993. Effects of entanglement and escape from high-seas driftnets on rates of natural mortality of North Pacific albacore, *Thunnus alalunga*. Fish. Bull., U.S. 91:798–803. . . . . . . . . 9319

## TABLE OF CONTENTS (CONTINUED)

BRILL, R. W., D. B. HOLTS, R. K. C. CHANG, S. SULLIVAN, H. DEWAR, AND F. G. CAREY.

1993. Vertical and horizontal movements of striped marlin (*Tetrapturus audax)* near the Hawaiian Islands, determined by ultrasonic telemetry, with simultaneous measurement of oceanic currents. Mar. Biol. 117:567–574. ............ 9320

BUSBY, M. S., AND D. A. AMBROSE.

1993. Development of larval and early juvenile pygmy poacher, *Odontopyxis trispinosa*, and blacktip poacher, *Xeneretmus latifrons* (Scorpaeniformes: Agonidae). Fish. Bull., U.S. 91:397–413.................................. 9321

BUTLER, J. L., P. E. SMITH, AND N. C.-H. LO.

1993. The effect of natural variability of life-history paramaters on anchovy and sardine population growth. Calif. Coop. Fish. Inves. Rep. 34:104–111........ 9322

CAILLIET, G. M., D. B. HOLTS, AND D. BEDFORD.

1993. A review of the commercial fisheries for sharks on the west coast of the United States, p. 13–29. *In* J. Pepperell, J. West, and P. Woon (eds.), Shark conservation. Proceedings of an international workshop on the conservation of elasmobranchs held at Taronga Zoo, Sydney, Australia, 24 February 1991. .................................................. 9323

CHESS, JAMES R.

1993. Effects of the stipe-boring amphipod *Peramphithoe stypotrupetes* (Corophioidea: Ampithoidae) and grazing gastropods on the kelp *Laminaria setchellii*. J. Crustacean Biol. 13(4):638–646. ..................... 9324

CHIVERS, S. J., AND A. C. MYRICK.

1993. Comparison of age at sexual maturity and other reproductive paramaters for two stocks of spotted dolphin, *Stenella attenuata*. Fish. Bull., U.S. 91:611–618. ....................................................... 9325

CRAIG, P., B. PONWITH, F. AITAOTO, AND D. C. HAMM.

1993. The commercial, subsistence, and recreational fisheries of American Samoa. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):109–116. ........................... 9326

DAILEY, M. D., M. L. FAST, AND G. H. BALAZS.

1993. *Hapalotrema dorsopora* sp. n. (Trematoda: Spirorchidae) from the heart of the green turtle (*Chelonia mydas*) with a redescription of *Hapalotrema postorchis*. J. Helminthol. Soc. Wash. 60(1):5–9. ......................... 9327

## TABLE OF CONTENTS (CONTINUED)

DAVENPORT, J., G. H. BALAZS, J. V. FAITHFULL, AND D. A. WILLIAMSON.
1993. A struvite faecolith in the leatherback turtle *Dermochelys coriacea* Vandelli: a means of packaging garbage? J. Herpetol. 3:81–83. . . . . . . . . . . . . . . . 9328

DeMARTINI, E. E.
1993. Modeling the potential of fishery reserves for managing Pacific coral reef fishes. Fish. Bull., U.S. 91:414–427.. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9329

DeMARTINI, E. E., D. M. ELLIS, AND V. A. HONDA.
1993. Comparisons of spiny lobster *Panulirus marginatus* fecundity, egg size, and spawning frequency before and after exploitation. Fish. Bull., U.S. 91:1–7. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9330

EDWARDS, E. F. AND C. PERRIN.
1993. Effects of dolphin group type, percent coverage, and fleet size on estimates of annual dolphin mortality derived from 1987 U.S. tuna-vessel observer data. Fish. Bull., U.S. 91:628–640.. . . . . . . . . . . . . . . . . . . . . . . . . . 9331

EVERETT, W. T., AND R. L. PITMAN.
1993. Status and conservation of shearwaters of the North Pacific. *In* K. Vermeer, K. T. Briggs, K. H. Morgan, and D. Siegel-Causey (eds.), The status, ecology, and conservation of marine birds of the North Pacific, p. 93–100. Can. Wildl. Serv. Spec. Publ., Ottawa. . . . . . . . . . . . 9332

FORNEY, K. A. AND J. BARLOW.
1993. Winter abundance estimates for cetaceans along the California coast based on a 1991 aerial survey. Rept. int. Whal. Commn 43:407–415. . . . . . . . . . . 9333

FRAGA, S., AND A. BAKUN.
1993. Global climate change and harmful algal blooms: the example of *Gymnodinium catenatum* on the Galician coast. *In* T. J. Smayda and Y. Shimizu (eds.), Toxic phytoplankton blooms in the sea, p. 59–65. Elsevier Science Publishers B.V. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9334

GERRODETTE, T.
1993. TRENDS: Software for a power analysis of linear regression. Wildl. Soc. Bull. 21:515–516. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9335

GILMARTIN, W. G., T. C. JOHANOS, AND L. L. EBERHARDT.
1993. Survival rates for the Hawaiian monk seal (*Monachus schauinslandi).* Mar. Mamm. Sci. 9(4)407–420. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9336

## TABLE OF CONTENTS (CONTINUED)

GILPATRICK, J. W., JR.
1993. Method and precision in estimation of dolphin school size with vertical aerial photography. Fish. Bull., U.S. 91:641–648. .................... 9337

GRIGG, R. W.
1993. Precious coral fisheries of Hawaii and the U.S. Pacific islands. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):50–60. .............................. 9338

HAIGHT, W. R., D. R. KOBAYASHI, AND K. E. KAWAMOTO.
1993. Biology and management of deepwater snappers of the Hawaiian Archipelago. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):20–27. ...................... 9339

HAIGHT, W. R., J. D. PARRISH, AND T. A. HAYES.
1993. Feeding ecology of deepwater lutjanid snappers at Penguin Bank, Hawaii. Trans. Am. Fish. Soc. 122:328–347. .............................. 9340

HAMM, D. C.
1993. The Western Pacific Fishery Information Network: a fisheries information system. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):102–108. ............... 9341

HANAN, D. A., D. B. HOLTS, AND A. L. COAN, JR.
1993. The California drift gill net fishery for sharks and swordfish, 1981–82 through 1990–91. Calif. Dep. Fish Game Fish Bull. 175, 95 p. ............... 9342

HENSLEY, R. A., AND T. S. SHERWOOD.
1993. An overview of Guam's inshore fisheries. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):129–138. .............................................. 9343

HEWITT, R. P., AND D. A. DEMER.
1993. Dispersion and abundance of Antarctic krill in the vicinity of Elephant Island in the 1992 austral summer. Mar. Ecolog. Prog. Ser. 99:29–39. ......... 9344

HINCKLEY, S., K. BAILEY, S. PICQUELLE, M. YOKLAVICH, AND P. STABENO.
1993. Age-specific mortality and transport of larval walleye pollock *Theragra chalcogramma* in the western Gulf of Alaska. Mar. Ecol. Prog. Ser. 98:17–29. ..................................................... 9345

## TABLE OF CONTENTS (CONTINUED)

HIRUKI L. M., W. G. GILMARTIN, B. L. BECKER, AND I. STIRLING.
1993. Wounding in Hawaiian monk seals (*Monachus schauinslandi*). Can. J. Zool. 71:458–468. . . . . . . . . . 9346

HIRUKI, L. M., I. STIRLING, W. G. GILMARTIN, T. C. JOHANOS, AND B. L. BECKER.
1993. Significance of wounding to female reproductive success in Hawaiian monk seals (*Monachus schauinslandi*) at Laysan Island. Can. J. Zool. 71:469–474. . . . . . . . . . 9347

HOLTS, D., AND D. W. BEDFORD.
1993. Horizontal and vertical movements of the shortfin mako shark, *Isurus oxyrinchus*, in the southern California bight. Aust. J. Mar. Freshwater Res. 44:901–909. . . . . . . . . . 9348

HUMPHREYS, R. L., JR., M. A. CROSSLER, AND C. M. ROWLAND.
1993. Use of a monogenean gill parasite and feasibility of condition indices for identifying new recruits to a seamount population of armorhead *Pseudopentaceros wheeleri* (Pentacerotidae). Fish. Bull., U.S. 91:455–463. . . . . . . . . . 9349

HUNTER, J. R. AND N. C. H. LO.
1993. Ichthyoplankton methods for estimating fish biomass introduction and terminology. Bull. Mar. Sci. 53(2):723–727. . . . . . . . . . 9350

HUNTER, J. R. AND T. WADA (EDS.).
1993. Part 1. Coastal pelagic fishes (report of working group 3). *In* PICES Scientific Report No. 1, p. i-24 North Pacific Marine Science Organization (PICES), c/o Institute of Ocean Sciences, Sidney, B.C., Canada. . . . . . . . . . 9351

JACOBSON, L. D., AND J. R. HUNTER.
1993. Bathymetric demography and management of Dover sole. N. Am. J. Fish. Manage. 13(2):405–420. . . . . . . . . . 9352

JACOBSON, L. D., AND C. J. THOMSON.
1993. Opportunity costs and the decision to fish for northern anchovy. N. Amer. J. Fish. Manage. 13:27–34. . . . . . . . . . 9353

JONES, D. R., R. W. BRILL, AND P. G. BUSHNELL.
1993. Ventricular and arterial dynamics of anaesthetised and swimming tuna. J. exp. Biol. 182:97–112. . . . . . . . . . 9354

## TABLE OF CONTENTS (CONTINUED)

LENARZ, W. H.
1993. Overview of the groundfish fisheries of the west coast of the United States of America. *In* 12ª Semana das Pescas dos Azores, 16 a 20 de Marco, Horta-Faial, Relatorio 1992, p. 215–219. .......... 9355

LO, N. C.-H., J. R. HUNTER, H. G. MOSER, AND P. E. SMITH.
1993. A daily fecundity reduction method of biomass estimation with application to Dover sole *Microstomus pacificus*. Bull. Mar. Sci. 53(2):842–863. ....... 9356

MACEWICZ, B. J., AND J. R. HUNTER.
1993. Spawning frequency and batch fecundity of jack mackerel, *Trachurus symmetricus*, off California during 1991. Calif. Coop. Oceanic Fish. Inv. Rep. 34:112–121. .......... 9357

MacFARLANE, R. B., E. C. NORTON, AND M. J. BOWERS.
1993. Lipid dynamics in relation to the annual reproductive cycle in yellowtail rockfish (*Sebastes flavidus*). Can. J. Fish. Aquat. Sci. 50(2):391–401. .......... 9358

MIYA, R. K., AND G. H. BALAZS.
1993. Ecology and conservation of green turtles in the nearshore waters of Waikiki Beach. 'Elepaio 53(2):9–13. .......... 9359

MOFFITT, R. B.
1993. Deepwater demersal fish. *In* A. Wright and L. Hill (eds.), Nearshore marine resources of the South Pacific, p. 73–95. Institute of Pacific Studies, Suva, Fiji. .......... 9360

MOSER, H. G., AND P. E. SMITH.
1993. Larval fish assemblages and oceanic boundaries. Bull. Mar. Sci. 53(2):283–289. .......... 9361

MOSER, H. G., AND P. E. SMITH.
1993. Larval fish assemblages of the California Current region and their horizontal and vertical distributions across a front. Bull. Mar. Sci. 53(2):645–691. .......... 9362

MYERS, R. F.
1993. Guam's small-boat-based fisheries. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2): 117–128. .......... 9363

# TABLE OF CONTENTS (CONTINUED)

NITTA, E. T., AND J. R. HENDERSON.
1993. A review of interactions between Hawaii's fisheries and protected species. *In* G. W. Boehlert (ed.), Fisheries of Hawaii and U.S.-associated Pacific islands. Mar. Fish. Rev. 55(2):83–92. . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9364

OKIHIRO, M. S., J. A. WHIPPLE, J. M. GROFF, AND D. E. HINTON.
1993. Chromatophoromas and chromatophore hyperplasia in Pacific rockfish (*Sebastes* spp.). Cancer Res. 53:1761–1769. . . . . . . . . . . . . . . . . . . . . . . . . . . . . . 9365

PARRISH, F. A., AND R. B. MOFFITT.

# Occurrence of an exceptional catch of pelagic juvenile lingcod (*Ophiodon elongatus*) off Point Reyes, California

PETER B. ADAMS, STEPHEN RALSTON AND THOMAS E. LAIDIG

*National Marine Fisheries Service, Southwest Fisheries Science Center, 3150 Paradise Drive, Tiburon, California, U.S.A. 94920*

## ABSTRACT

An exceptionally large catch of pelagic juvenile lingcod (*Ophiodon elongatus*) was made just offshore of Point Reyes, California in 1990. Results of 678 midwater trawls from annual surveys from 1983 to 1990 show that pelagic juvenile lingcod have a strong nearshore distribution and were most abundant in the Gulf of the Farallones, with a mean abundance of 5.0 per trawl. Otoliths from fish taken in the large catch were used to estimate parameters of a log-transformed Gompertz growth model, which was then used to calculate hatch dates. Hatching peaked around 24 March and ranged from 10 March to 19 April, implying a January–February spawning season for lingcod off central California. The large catch was associated with an anticyclonic eddy which would lead to water being trapped near the coast; convergence of fish associated with the eddy may have been due to either physical or biological effects.

**Key words:** anticyclonic eddy, larval abundance, lingcod, otoliths

## INTRODUCTION

Patchy spatial distributions are common in trawl surveys (Lenarz and Adams, 1980; Pennington, 1986) and are frequently most extreme in surveys of pelagic fishes (Smith and Hewitt, 1985). Here we report on the occurrence of an unusually large catch of pelagic juvenile young-of-the-year lingcod (*Ophiodon elongatus*) taken during a series of annual surveys conducted off central California. To estimate the hatch dates of the lingcod in this one catch we construct a growth model for the first 5 months of life. Local oceanographic features in the area at the time of the unusual catch are also described.

Lingcod have a complex form of reproduction (Cass *et al.*, 1990). In British Columbian waters, peak spawning occurs from January to February, after mature fish have migrated into shallow (< 30 m) rocky areas. Males establish territories and remain to guard a demersal egg mass until hatching is complete after 7 weeks. Larval lingcod hatch at a standard length (SL) of 7–9 mm and, while planktonic, undergo juvenile transformation at ≈20 mm SL. They remain pelagic until early summer, when they settle to benthic habitats at ≈70–80 mm SL.

## METHODS

Lingcod were collected incidentally during annual trawl surveys of pelagic juvenile young-of-the-year rockfish (*Sebastes* spp.). Since 1983, sampling has been conducted 1–4 times per year at a fixed series of stations off central California (Fig. 1, Table 1) using a 26 × 26 m

**Table 1.** Summary of midwater trawl surveys conducted for pelagic fishes off the central California coast (1983–90). See Wyllie Echeverria *et al.* (1990) for a detailed description.

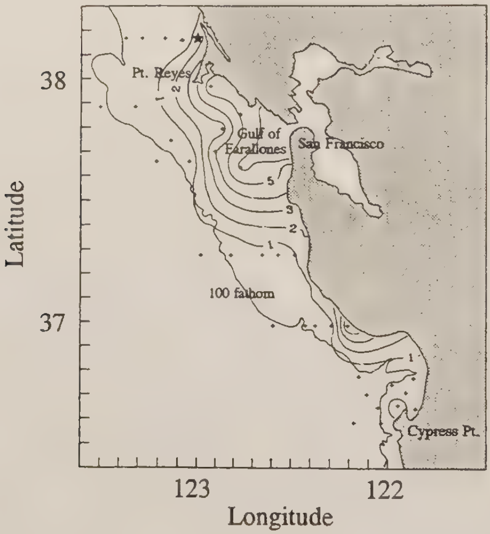
**Figure 1.** Spatial contours of the average number of lingcod caught per trawl (1983–90). The locations of the 36 standard stations upon which the lines are based are shown as plus signs. The location of the exceptional 29 May 1990 lingcod catch is marked with a star.



Cobb midwater trawl equipped with a 0.945 cm ($\frac{3}{8}$ inch) stretched-mesh inner liner. Depending on bottom depth, the net was towed horizontally with the headrope at 6 or 32 m below the water's surface for 15 minutes at a speed of 1.0 knot. Survey methods have been described in detail elsewhere (Wyllie Echeverria *et al.*, 1990).

To determine the overall spatial pattern of lingcod within the study region, the abundance of lingcod from all trawls, excluding one large and exceptional catch, was spatially contoured by kriging. Patchiness was measured using the negative binomial coefficient $\kappa$ (Jahn and Smith, 1987).

A series of 20 conductivity–temperature–depth (CTD) casts were made in a grid centered over the location of the exceptional lingcod catch. These casts were all completed within 24 h of the time the trawl was conducted and constituted a routine part of survey procedures (e.g. Schwing *et al.*, 1990). All CTD data were collected with a Sea-Bird Electronics SEACAT-SBE-19 profiler cast to maximum depths of 500 m. The CTD data were analysed by spatially contouring the density of water ($\sigma_t$) over a series of depths, particularly at 10 m (approximate depth of the tow).

In the laboratory, the SL of each fish was measured and sagittal otoliths were removed from 63 specimens that spanned the full size distribution of fish caught. Otoliths were processed following methods described in Laidig *et al.* (1991).

To supplement these samples, lingcod larvae were collected along the central California coast between Point Reyes and Cypress Point from 10 to 15 February 1991. Specimens were collected with a 1 m bongo net (505 $\mu$m mesh) using standard CalCOFI protocols (Smith and Richardson, 1977). Plankton samples were placed in 80% ethanol and larvae were later sorted in the laboratory where otoliths were removed.

Counts of daily increments in the otolith were initiated at the first dark check mark that both completely encircled the primordium and was subsequently enveloped by complete rings of smaller width. The otolith radius (OR) at this mark was 28.6 $\mu$m ($\pm$ 1.6 $\mu$m), which agreed well with a prediction of the size of the otolith at hatch (32.0 $\mu$m) produced from a regression of OR on SL and known size at hatch (7 mm SL; Giorgi, 1981).

The age and SL data were modeled with a four-parameter growth equation (Schnute, 1981). From the initial estimates, the model was simplified to the three-parameter Gompertz growth function. The log-transformed version of the equation was fitted owing to heteroscedastic variance (Zweifel and Lasker, 1976), i.e.

$$\log_e [SL] = \log_e [l_0] + \mathrm{k}(1 - e^{-gt}) \qquad (1)$$

where $l_0$ is length at birth, k is instantaneous rate of growth, $g$ is the rate of decrease of k, and $t$ is age (days). Using Giorgi's (1981) estimate of size at hatch, the intercept term in the final fit was fixed at $l_0 = 7.0$ mm. The inverse of the fitted growth model was used to predict the age of each lingcod taken in the trawl. The distribution of hatching dates was then calculated by subtracting each predicted age from the date of capture.

## RESULTS

Pelagic juvenile lingcod were most abundant in the Gulf of the Farallones and showed a strong nearshore distribution (Fig. 1). Contour plots showed mean abundances of 5.0 lingcod per trawl at depths less than 50 m in the Gulf of the Farallones, decreasing to 1.0 per trawl in deeper waters. Pelagic juveniles were not taken off the continental shelf, i.e. deeper than 183 m (100 fathom contour).

Juvenile lingcod have a very patchy distribution ($\kappa = 0.03$). This low value of $\kappa$ is influenced greatly by one exceptional catch of 230 fish made on 29 May 1990 at

04:15 just offshore of Point Reyes, California (location marked in Fig. 1). This one sample represented 0.148% of the 678 trawls conducted from 1983 to 1990, but accounted for 29.7% of all lingcod captured. The 230 fish from this trawl compare with an overall mean of 0.97 lingcod/trawl (SE = 0.23) taken in the remaining 677 trawls. Moreover, the fish demonstrated a wide size range, from a minimum of 25.7 mm SL to a maximum of 77.1 mm SL. The size distribution peaked between 50 and 60 mm, and was slightly skewed toward larger fish.

The fit of the log-transformed Gompertz equation to the age data was good (Fig. 2; $F_{0.05} = 49778.0$, d.f. = 2,63; $r^2 = 0.854$). Parameter estimates were $\hat{k} = 3.669 \pm 0.316$ and $\hat{g} = 0.0124 \pm 0.0016$ day$^{-1}$. Although not used in fitting the model, we have included in the figure the age data from four larvae sampled in 1991. The proximity of the data to the regression line suggests that the juvenile equation may also apply to larval lingcod.

The estimated hatch date distribution of fish from the large sample peaked around 24 March and ranged from 10 March to 19 April (Fig. 3). The distribution had a wide spread of hatch dates; the extremes ranged over 40 days, indicating that the lingcod in the catch did not come from one egg mass.

A geostrophic interpretation of the density field ($\sigma_t$) at several depths offshore of Point Reyes suggests that an anticyclonic eddy existed south-west of the site of the large lingcod catch (Fig. 4). Clockwise circulation of this eddy would transport water coastally and create a nearshore region of diminished stagnant flow. Anticyclonic flow immediately north of Point Reyes has been observed during the upwelling season (Schwing *et al.*, 1990). The area is directly inshore of a persistent streamer of cold upwelled water that moves south along the coast of northern California and offshore at Point Reyes (Schwing *et al.*, 1991). Water trapped near the coast off Tomales Point contrasts with strong southerly flow offshore.

**Figure 2.** Predicted length (SL) from the log-transformed Gompertz equation as a function of age in days (solid curve). The open circles are lengths versus age data used in the model fit. The filled squares are data from four larvae sampled in 1991, which were not included in the fit.

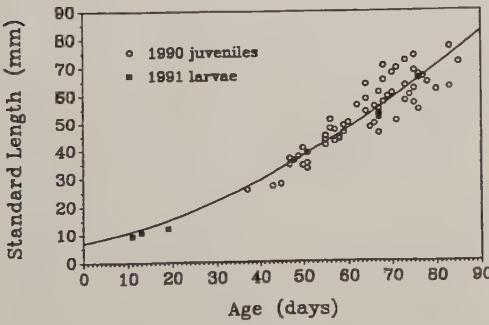


**Figure 3.** Frequency distribution of hatch dates for 230 juvenile lingcod taken in the 29 May 1990 sample.

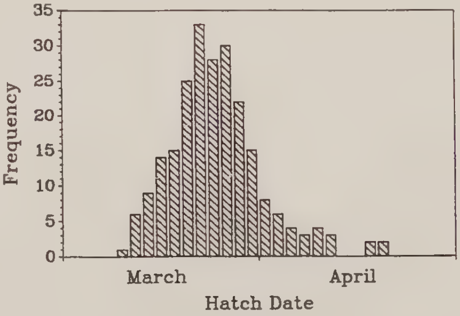
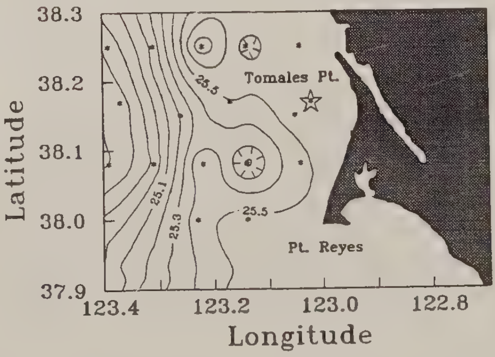


## DISCUSSION

The data presented here indicate that lingcod off central California hatch during March and April, grow rapidly, and are patchily distributed nearshore as juveniles. Hatching during March and April implies a January–February spawning season for lingcod, assuming that 7 weeks represents the length of the demersal egg stage (Cass *et al.*, 1990). These findings are consistent with reported spawning dates of mid-January to mid-

**Figure 4.** Spatial contouring of the density of water ($\sigma_t$) at 10 m depth from a series of 20 CTD casts made on 28–29 May 1990. The location of the large lingcod catch is marked with a star. Seventeen of the 20 CTD locations are shown as asterisks; the remaining three occurred just west of the figure.



February and hatch dates of mid-March to April for lingcod in British Columbia (Cass *et al.*, 1990).

Lingcod growth during the pelagic juvenile stage is rapid; fish reach 70 mm SL in 80 days. Also, the Gompertz growth model provided a good fit and it may be possible to extend it to other years, because the ages and lengths of four larval fishes caught in 1991 (Fig. 2) lay close to the regression.

Pelagic juvenile lingcod are distributed in a very patchy manner. The estimated negative binomial coefficient ($\hat{k} = 0.03$) is quite low for pelagic early life history stages, which are typically $< 0.4$ (Jahn and Smith, 1987). Adult groundfish values usually range from 0.1 to 1.0 (Lenarz and Adams, 1980).

Beyond suggesting an association with the eddy, we cannot provide an explanation for the occurrence of this unusual catch. The convergent effect of the eddy may have been due to either physical or biological mechanisms. For example, passive drifters transported south in the persistent offshore current could be shunted to the stagnant water near the coast where they could accumulate. A biological explanation is that the eddy somehow resulted in conditions favorable to the survival of juvenile lingcod. Either explanation is consistent with the observed wide distribution of hatch dates.

## ABSTRACT

We used the diet of a seabird, the common murre (*Uria aalge*), to assess the abundance of juvenile rockfish (*Sebastes* spp., mostly *S. jordani*) in the Gulf of the Farallones, California, 1973–90. On the basis of an exploratory analysis of the data and of several oceanographic factors, we hypothesize that availability of fish in the study area during June–July was a function of advection during the January–February period of rockfish parturition. When upwelling or downwelling was persistent in winter, there were few juveniles in late spring, but when upwelling had been mild or pulsed, juveniles were abundant. Rockfish availability also decreased when turbulence, sea level, and sea-surface temperature were high during winter. Stepwise multiple regression analyses indicated that, among these variables, advective transport significantly affects the distribution of juvenile rockfish.

## RESUMEN

Usamos la dieta del ave marina alca piquilarga (*Uria aalge*) para estimar la abundancia de rocot juveniles (*Sebastes* spp., principalmente *S. jordani*) en el Golfo de Farallones, California, 1973–90. Basándonos en un análisis exploratorio de los datos así como en factores oceanográficos, presentamos la hipótesis que la disponibilidad de peces en Junio–Julio fué función de la advección durante Enero–Febrero (la temporada de cría los rocot). Cuando hubo surgencias o hundimientos de masas de agua persistentes en invierno, disminuyó la abundancia de juveniles en primavera tardía, mientras que cuando las surgencias fueron poco intensas u ocurrieron intermitentemente, la abundancia de los juveniles incrementó. La disponibilidad de los rocot disminuyó cuando en invierno hubo valores altos de turbulencia, nivel del mar o temperatura superficial. Análisis de regresión múltiple por pasos indicaron que de entre ésas variables, la advección afecta significativamente la distribución de rocot juveniles.

## INTRODUCTION

Eastern boundary currents contribute roughly a third of the world's fishery resources (Thompson 1981). Such productivity is attributable, in part, to the dominant oceanographic feature of these areas — upwelling of cold, nutrient-rich waters to the surface, which in turn leads to enhanced phytoplankton growth. Parrish and MacCall (1978) examined the relations between several environmental variables and the recruitment success of Pacific mackerel (*Scomber japonicus*) in southern California, and found the highest correlation with the upwelling index (Bakun 1973) at 30°N during the early part of the spawning season. The correlation was positive, and Parrish and MacCall stated that "upwelling is obviously related to recruitment, because it determines the basic productivity of the California Current."

Associated with upwelling, however, is wind-generated turbulence, which could lead to impaired nutrient and carbon transfer to higher trophic levels. For example, Peterman and Bradford (1987) found a negative linear relationship between the mortality rate of northern anchovy (*Engraulis mordax*) during the first 15 days of the larval period and a measure inversely related to turbulence, i.e., the number of periods of calm at 33°N during the main spawning season. Neither cannibalism, as measured by the biomass of adults, nor advection, as measured by offshore Ekman transport, improved the explanation of variability in early mortality. Further, as noted by Methot (1983), even though advection may not have increased mortality during the first 15 days of the larval period, it may have reduced the proportion of larvae that remain in favorable habitat, thereby contributing to late mortality.

Bailey and Francis (1985) found strong year classes of Pacific whiting (*Merluccius productus*) only when sea-surface temperature (SST) in the Los Angeles Bight was relatively high, and when upwelling at 36°N was relatively low at the beginning of the spawning season. They showed that whiting larvae are found farther offshore and to the south in cold years and in years of relatively high upwelling. They concluded that this could be either because spawning takes place farther offshore and to the south or

---

[Manuscript received April 1991.]

because of advection. They cited evidence that the larvae grow more slowly during cold years and that prey densities are relatively low offshore and to the south.

Fishery oceanographers have long believed that advection could be an important factor in the reproductive success and recruitment of fish. Bakun (1986) and Simpson (1987) discuss some of the physical mechanisms involved in advection and some physical phenomena that would retain eggs and larvae in favorable habitat.

In order to deter the offshore transport of larvae, fishes in eastern boundary currents tend to reproduce when advection (Ekman transport) is low. They also tend to bear their young alive; relatively large larvae are more capable of swimming than, for instance, newly hatched northern anchovies (Parrish et al. 1981). We found that prevalence of the young-of-the-year (YOY) of one genus of live-bearing fish, *Sebastes*, varies from year to year in the diet of an apex predator, the common murre (*Uria aalge*), in California (Ainley and Boekelheide 1990). To determine what factors might explain the availability of rockfish, we analyzed the relations between several oceanographic factors and the prevalence of rockfish in the murre diet.

## METHODS

A seabird, the common murre, was our fish-sampling tool. We studied murre diet at Southeast Farallon Island (SEFI), 42 km offshore of central California (figure 1), each June and July for 18 years, 1973–90. Murres carry fish in their beaks, in full view, to feed their offspring. From within a blind that overlooked a group of approximately 100 pairs of breeding murres within 10 m of the blind, we observed birds returning from the sea with fish (Ainley and Boekelheide 1990). Observations were made every 3 to 5 days throughout the chick-rearing season, from late May to early July. Using 8 × binoculars (for a "frame-filling" view of each murre), we identified, to the closest taxon possible, 800 to 4000 prey items per year (Ainley and Boekelheide 1990). Years when sample sizes were smaller were oceanographically anomalous years, such as during El Niño events, when fewer pairs were breeding (Ainley and Boekelheide 1990).

We used the proportion of juvenile rockfish in the diet as an index to rockfish availability within the foraging range of the murres. Murres' preferred prey were juvenile rockfish (Ainley and Boekelheide 1990). When rockfish were not available, the murres fed along the mainland coast on other species of fish, principally anchovies. Murres dive to a depth of about 100 m, which corresponds to the depth of the continental shelf in the study area. They forage up to 80 km from breeding sites. Thus, allowing for the shape of the mainland coastline and the fact that it lies only about 40 km from SEFI, the murre population can sample about 7000 km$^2$ of ocean during the summer breeding season, including the entire volume of water overlying the continental shelf and upper slope.

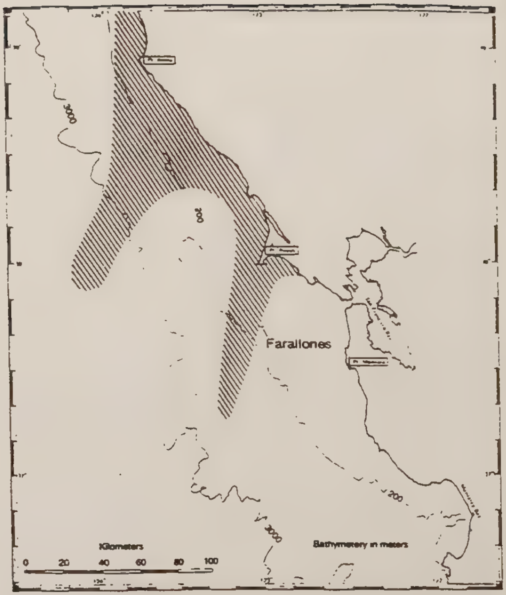

Figure 1. Upwelling plumes of a size and shape typical of early spring in central California, and the location of the Gulf of the Farallones study area (shape of the plume drawn according to figure 4.2.2-27 in SAIC 1987).

During June 1985 and 1986, we collected 24 and 42 common murres, respectively, at various locations within the study area. Gut contents analysis revealed 274 juvenile rockfish in the 1985 sample, and 87 in the 1986 sample (PRBO unpubl. data), and many rockfish were fresh enough to identify to species. These data provided a check for the identifications made at SEFI.

From 1983 to 1991, the National Marine Fisheries Service, Tiburon Laboratory (NMFS), estimated the abundance and distribution of juvenile rockfish in waters off central California, including those surrounding the Farallon Islands (our murres were collected on these cruises). The more classical research method used by NMFS—a grid of trawl stations during late May and June (Wyllie Echeverria et al. 1990; Adams 1992)—overlapped the time of our observations at SEFI. The proportion of juvenile rockfish in the murre diet (as a measure of annual variability in the abundance of the fish) correlated with the NMFS trawl data during overlapping years when trawl results were consistently derived from year to year (1986–91, including 1991 to increase the sample size); a regression between murre diet and log-transformed trawl results for fishes in the size classes appropriate to murre foraging (>39 mm; see Results) was highly significant ($R^2 = 0.87$, $t = 5.27$, $P < 0.01$; figure 2). Therefore, we believe that the bird diet serves as a valid index to the availability of juvenile rockfish in the Gulf of the Farallones region during early summer. We use the diet data for comparison with oceanographic conditions because this time series is much longer than that of the trawl data.

We related the proportion of rockfish in the murre diet to indices of upwelling ($m^3/sec^{-1}/100\ m^{-1}$ of coastline; Bakun 1973) and turbulence (wind speed$^3$), SST, and sea level. We used the upwelling index as a surrogate measure of Ekman transport (advection). Monthly upwelling indices were taken from Bakun (1973), Mason and Bakun (1986), and unpublished updates. A turbulence index consisting of monthly wind-speed-cubed values was derived from 6-hr wind-speed values that were inferred by Bakun from atmospheric pressure fields supplied by the U.S. Navy's Fleet Numerical Oceanography Center. A preliminary analysis with these data indicated that the upwelling index and turbulence estimates derived for 36°N are more representative of conditions in the study area than those at 39°N (F. Schwing, Pacific Fisheries Environmental Group, NMFS, Monterey, pers. comm.). At SEFI we measured SST daily. We used sea level measured at San Francisco (units in mm) as an index to the strength of northerly flow in the California Current and an integration of temperature by depth and region—factors known to affect the marine climate of eastern boundary currents (Norton et al. 1985). Finally, we related rockfish values to measures of wind pulsation, defined as the number of wind events (velocity >9 kts terminated by winds <9 kts) per month. At SEFI we measured winds daily at 0800 PST.

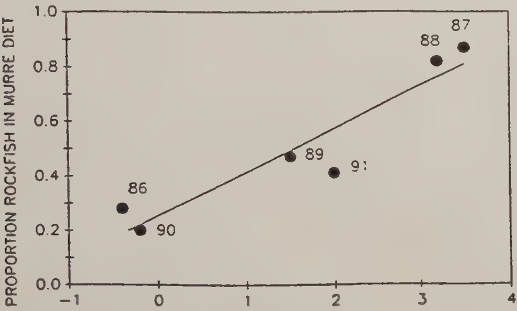

Figure 2. The relation between the proportion of the murre diet contributed by rockfish and the log of the number of juvenile rockfish (>39 mm) in NMFS trawl samples, 1983–91. The relation is described by the equation, $Y = 0.272 + 0.165X$.

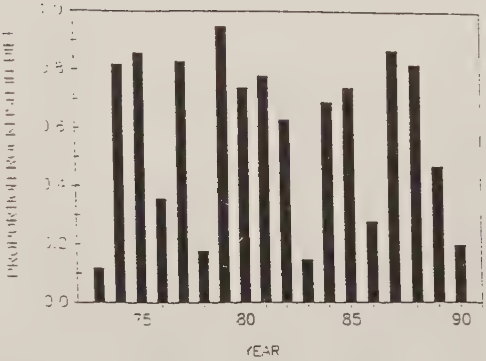

Figure 3. Annual variability in the proportion of rockfish in the diet of the common murre, Southeast Farallon Island, June and July 1973–90.

We correlated the percentage of rockfish in the birds' diet with the above oceanographic and meteorological values averaged for individual and combined monthly periods, October to June, preceding the June–July chick-feeding period. Initially, we used simple regression analyses to investigate relations among these variables; we also tested for correlations among the measures. We used quadratic values of upwelling, turbulence, and SST to model apparent curvilinear relations. To examine the relative effect of each oceanographic variable on rockfish availability, we used forward and backward stepwise multiple regression. Statistical significance was assumed if nominal $P < 0.05$. We recognized that the large number of tests increases the probability of failing to reject false hypotheses, and thus consider this an exploratory analysis.

## RESULTS

Rockfish in the common murre diet varied substantially from one year to the next (figure 3). Regression analyses of rockfish in the diet against the upwelling index, turbulence, SST, and sea level indicated which values provided significant correlations (figure 4). The average January-plus-February upwelling index ($UJ+F$) related to rockfish availability in a parabolic fashion (figure 5) and explained 61% of the variation in interannual abundance ($Y = 79.54 + 1.51\,(UJ+F) - 0.11\,((UJ+F)^2)$; separately, neither month was significantly related to rockfish abundance. Rockfish were most available when the

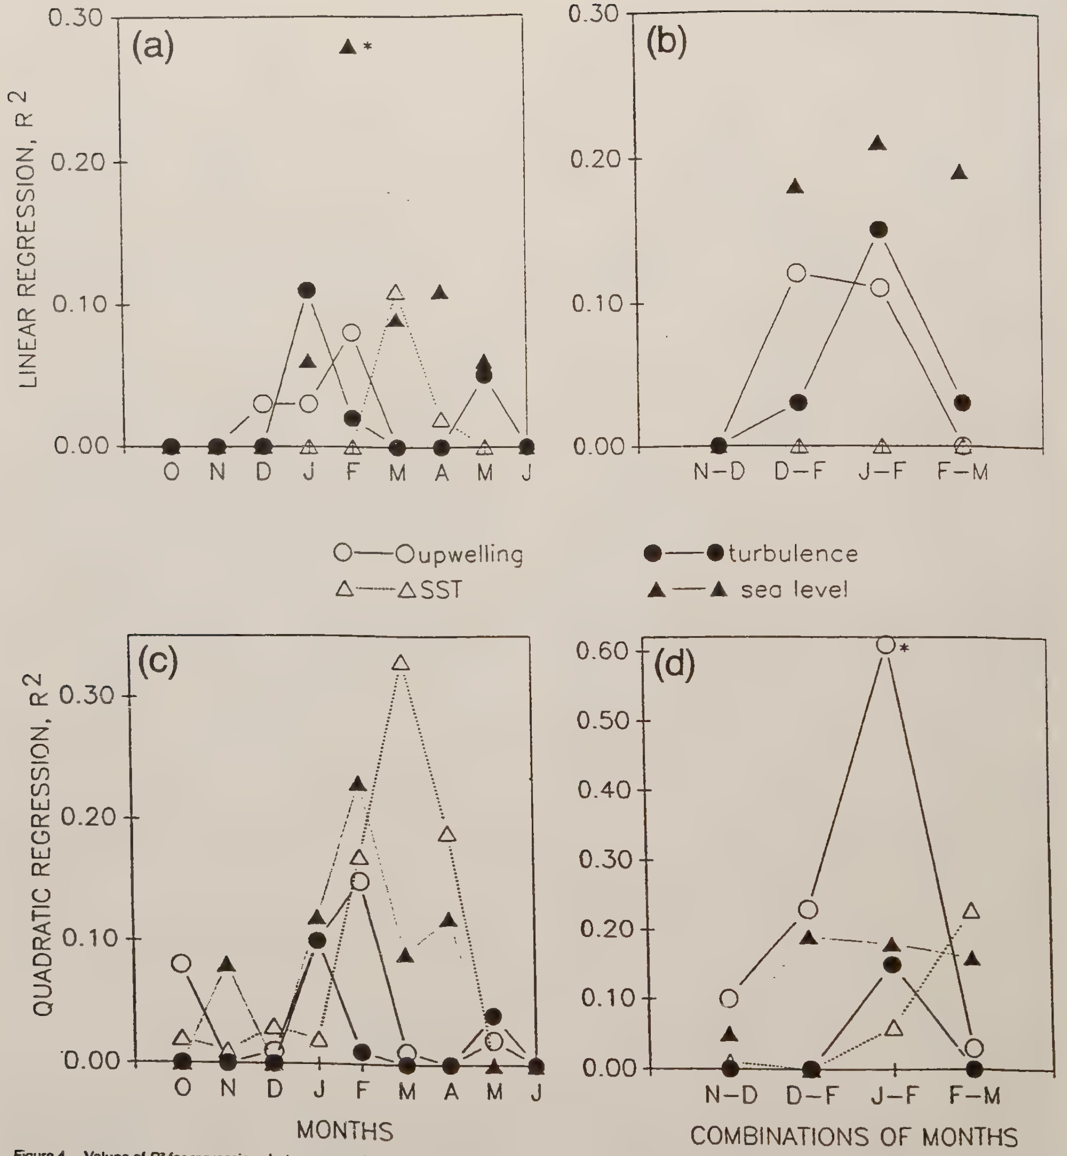

Figure 4. Values of $R^2$ for regressions between prevalence of rockfish in the murre diet and four oceanographic parameters: *a*, linear regression by month, and *b*, by combinations of months; *c*, quadratic regression by month, and *d*, by combinations of months. Significant values are indicated by an asterisk (*).

average January–February upwelling index was slightly above zero. During years of prevalent winter downwelling (1973, 1978, 1983, and 1986), or years when winter upwelling was overly persistent (1976, 1989, 1990), rockfish were less abundant (figure 3; see also Ainley and Boekelheide 1990). We found no significant relations between rockfish abundance and monthly upwelling indices later in the spring and summer, when upwelling reaches its maximum intensity in the California Current sys-

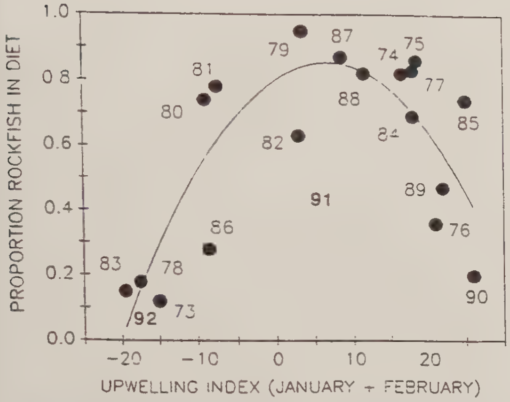

Figure 5. Parabolic relation between rockfish in the diet of murres in the Gulf of the Farallones during June and July and the upwelling index during the preceding January and February, 1973–90. The relation is described by the equation $Y = 79.54 + 1.51(UJ + F) - 0.11((UJ + F)^2)$.

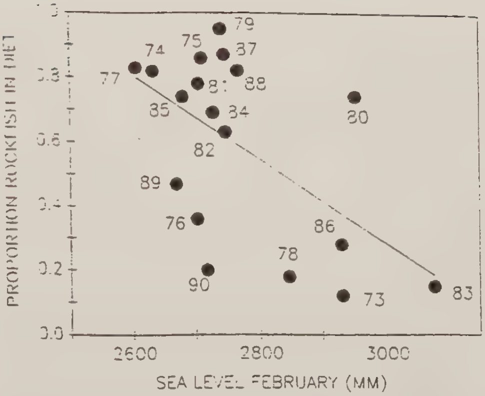

Figure 6. The relation between rockfish in the diet of murres in the Gulf of the Farallones during June and July and sea level during the preceding February, 1973–90.

tem (Breaker et al. 1983). Neither did we find any relation with wind pulsation.

Rockfish availability was negatively, but not significantly, correlated with turbulence during January–February (figure 4; $P = 0.0635$). This variable accounted for only 15% of the yearly variation in fish prevalence. Again, separate turbulence values for January or February were even more weakly related to rockfish availability. Turbulence was greatest during 1978, 1980, 1983, and 1986; the winters of 1978, 1983, and 1986 were also characterized by intense downwelling and elevated sea level. We detected no departure from linearity ($P > 0.10$) between turbulence and rockfish availability.

In March, SST was negatively, but weakly, correlated with rockfish abundance. The quadratic of March SST accounted for 33% of the variation in annual rockfish prevalence, but was again not significant (figure 4; $P = 0.052$). The warmest March SSTs were noted in 1978, 1983, and 1986.

Sea level during February was negatively and significantly correlated with rockfish prevalence (figures 4 and 6; $P = 0.014$), when it accounted for 28% of the yearly variation in rockfish abundance. Sea level was highest in 1973, 1978, 1980, 1983, and 1986. Although sea level in 1976, 1989, and 1990 was low, rockfish were scarce. A linear relation was more significant and explained more of the variance than did a quadratic relation.

The January–February upwelling index, March SST, February sea level, and January–February turbulence values correlated significantly (table 1). The upwelling index was negatively correlated with SST, sea level, and turbulence. SST was positively correlated with sea level and turbulence, and sea level and turbulence also were positively associated. Forward multiple regression indicated that January–February turbulence ($F = 0.10$), March SST ($F = 0.25$), and February sea level ($F = 0.80$) were insignificant when January–February upwelling was first entered into the model. A backward regression analysis confirmed these findings (table 2). The explan-

TABLE 1

**Correlation Coefficients among Four Environmental Factors in Central California, 1973–90**

| | 1 | 2 | 3 | 4 |
|---|---|---|---|---|

| SST | 0.11 | 3.08 | 0.0986 |

$R^2$ values were adjusted by the degrees of freedom and sample size ($n$ = 18 years).

atory power of the model was greatest when only the upwelling index was included. SST and sea level contributed little to explaining variation in rockfish prevalence in the diet and could be dropped from the model with no effect on $R^2$ values.

## DISCUSSION

Most of the rockfish eaten by murres at Southeast Farallon are YOY shortbelly rockfish (*S. jordani*) — on average, 70% of rockfish in the summer diet (Ainley and Boekelheide 1990). This species has also dominated midwater trawl catches of YOY rockfish in the study area (Wyllie Echeverria et al. 1990; Adams 1992), as well as the fish contained in murre stomachs during the two years of collections (Briggs et al. 1987; Ainley, unpublished data). The shortbelly constitutes the largest biomass of any rockfish off California and is a species of the continental shelf and upper slope (Pearson et al. 1991). January and February are the peak months of parturition for this and most other abundant rockfish species that inhabit offshore central California (Wyllie Echeverria 1987), and are the months just before the spring transition from winter conditions to the upwelling period (Breaker et al. 1983). Murres begin to feed on these fish, along with other prey of the same size, as soon as the prey appear in winter (PRBO unpublished data). By the time the rockfish have increased from about 1 cm to 4 cm they are big enough to be carried to chicks at SEFI breeding sites.

The correlation with the upwelling index indicates to us that intense and persistent midwinter winds, either onshore (negative upwelling) or offshore (positive upwelling), transport larvae and perhaps small juveniles away from the foraging range of murres at the Farallones. It is at this time, just after birth and when they are smallest, that YOY rockfish are most vulnerable to advection. Figure 1 depicts an upwelling plume typical of this coast during the early upwelling period (March–April; see also figure 3 in Parrish et al. 1981). Later (June), when upwelling is intense and continuous, plumes in this area of the coast are much broader and extend much farther offshore (SAIC 1987). Along this coast, murres tend to feed at the periphery of upwelling plumes, because there are no prey in recently upwelled water (Briggs et al. 1988). On the basis of this pattern and our analysis herein, we conjecture that large, intense plumes may completely displace YOY rockfish from the foraging range of Farallon-based murres. Advection outside of the murre foraging range — i.e., away from the continental slope (the main habitat of shortbelly and certain other rockfish) — may remove young rockfish from the population unless they can compensate by swimming, or survive until fortuitous currents carry them back to suitable habitat. Whether or not such advection strongly affects recruitment of rockfish, however, remains to be determined (and is being investigated by NMFS). Hobson and Howard (1989) reported mass mortality of YOY shortbelly rockfish on the California shore, not the usual shortbelly habitat (and certainly outside of murre foraging habitat), and conjectured that they had been transported in waters propelled by intense shoreward winds.

Upwelling has the potential to increase primary production in coastal waters of eastern boundary currents, as well as to decrease the egg and larval survival of spawning pelagic fishes because of turbulence and advection (Bakun 1990; Cury and Roy 1989). Our analysis indicates that increased transport of young (larval and small) juvenile fish away from traditional areas for recruitment is an important factor. We base our hypothesis — "The observed pattern of presence or absence of fish is explained by advection" — partly upon the reasoning of Cury and Roy (1989): fish (in this case, rockfish) should bear their young within the central upwelling area of the California Current just before the seasonal onset of intense upwelling. By eliminating the passive (planktonic) egg and reducing the early larval stage, they should be better able to cope with turbulence and advection, which are also caused by the intense, upwelling winds that are the nemesis of smaller developmental stages of the fish. Indeed, by bearing their young alive, rockfish eliminate about 40 days' free existence in the passive stages. This idea assumes that incubation time would be the same as gestation time if rockfish spawned eggs rather than bearing viable larvae. If it is assumed that incubation time of (hypothetical) egg-laying rockfish would be similar to that of other egg layers, then only about one week of passive drifting would be eliminated.

On the other hand, many rockfish species apparently bear their young when they do in order to avoid the intense offshore transport characterizing late spring in the California Current region, as well as perhaps to take advantage of spring plankton blooms. Through natural selection, the release of rockfish larvae during late winter may have evolved because upwelling events are usually intermittent at that time. Upwelling events that are mild or short lead to an enhanced food web. Resulting upwelling plumes may displace the fish slightly offshore, but the young fish are able to return because, between the upwelling events, slack or onshore winds propel them or allow them to return shoreward. We failed to find a correlation with wind pulsation because years of extended weak transport and intermittent strong winds were those in which YOY rockfish were abundant. In such conditions the swimming ability of the young, but relatively well developed, rockfish larvae is sufficient to accommodate to the food dispersal caused by turbulence.

Our analyses suggest that advection is an important factor determining the occurrence patterns of YOY rockfish in central California. Other factors that perturb the oceanic environment in which these rockfish live also appear to play a role. These factors are represented by SST and sea level in our analyses and, like upwelling, correlated most closely with variability of YOY rockfish during late winter.

## ACKNOWLEDGMENTS

Our work on the Farallon National Wildlife Refuge was made possible through a contractual agreement and the logistic support of the U.S. Fish and Wildlife Service and the National Weather Service, as well as the generosity of the members of and donors to PRBO. PRBO participation in NMFS rockfish cruises was funded during various years by the Environmental Protection Agency, Fish and Wildlife Service, Gulf of the Farallones National Marine Sanctuary, Minerals Management Service, and PRBO itself. Collection of SST at SEFI was accomplished through our participation in a shore-station program managed by the Scripps Institution of Oceanography. Upwelling indices were supplied by D. Husby, Pacific Fisheries Environmental Group, NMFS, Monterey; sea-level data were supplied by G. Mitchum, University of Hawaii. We benefited from discussions of rockfish biology with R. Larson, A. MacCall, S. Ralston, D. Woodbury, and coworkers at the NMFS Tiburon Laboratory. Farallon biologists of PRBO, research personnel at the Tiburon Lab, and the officers and crew of the R/V *David Starr Jordan* aided immensely in the determination of rockfish abundance and murre diet. We thank S. Emslie and A. MacCall for their reviews and constructive comments on this and an earlier version. This is contribution no. 486 of PRBO.

# *Divergency between average and frontier production technologies: an empirical investigation for Bangladesh*

MOHAMMAD ALAUDDIN, DALE SQUIRES[‡] and CLEM TISDELL

*Department of Economics, University of Queensland, Brisbane, Queensland 4072, Australia,* and [‡]*National Marine Fisheries Service, Southwest Fisheries Science Centre, PO Box 271, La Jolla, CA 92038, USA*

Applied economic analysis and policy formation often relies on estimated production technologies. Primal representations of production technologies can be specified as the average production function or as the stochastic frontier. This paper uses nested and non-nested specification tests and assessment of economic variables, including elasticities and marginal products, to evaluate systematic differences between the average production function and three different specifications of the stochastic frontier. Bangladesh serves as an illustrative example. The importance emerges of first beginning any analysis of production technologies with nested hypothesis testing of inefficiency and non-nested hypothesis testing for systematic but unknown differences between the average and stochastic frontier functions followed by nested testing of the final form of the production technology.

## I. INTRODUCTION

In empirical work, the production function is usually estimated by regression analysis and, so, provides only an average relationship between inputs and output, since the regression line is fitted through the mean of the data set. In contrast, the estimation of production frontier corresponds to the formal economic definition of a production function (Tisdell 1982).[1] Applied policy formation based upon estimation of these two alternative representations of the production technology, the 'average' production function (hereafter the production function) and the production frontier, might lead to different policies and conclusions. Hence, an appreciation of the extent of differences of these estimates of the production function can be useful in practice.

The issue of possible differences in the assessment of the production technology by production functions and production frontiers is addressed in this paper. The approach adopted is an empirical one, using a cross-section of data for industries from Bangladesh, to estimate econometrically both an aggregate production function and an aggregate production frontier.[2] The results are used to assess differences in the substitution possibilities between labour and

---

[1] For a comprehensive discussion of conceptual issues in the measurement of economic and productive efficiencies see Tisdell (1985).

[2] The current analysis, like the similar analysis of Bairam (1988), does not really identify the (outer) production frontier of the economy, since the output, capital and labour quantities are amalgams. In most industries firms will vary in their technical efficiency, but this is 'concealed' when industry averages are used. Unfortunately, we do not have the data to estimate this 'outer' production frontier for the economy. But it is quite possible, for instance, that employment-generating/displacing effects of new capital when this outer frontier is considered could differ even more substantially from those suggested by the average aggregate production than do the estimates given here for the aggregate production frontier. This suggests that while the type of analysis may give some useful first approximations for policy purposes, that it needs to be supplemented by in-depth studies in industry economics. Furthermore, it may be important to take into account natural resource and sustainability aspects, e.g. role of natural resource stocks in production, before reaching firm policy conclusions from this type of production technology estimation.

0003–6846 © *1993 Chapman & Hall*

capital, differences in their marginal products, and any final form of the technology found from a series of nested hypothesis tests of constant returns to scale (CRTS) and functional form. Both nested and non-nested specification tests evaluate whether the frontier or production function is more appropriate. It is found that selection between the frontier and production function hinges upon the type of significance tests employed, nested or non-nested, and the initial null hypothesis.

## II. APPROACH AND METHODOLOGY

Technical efficiency and procedures for specification of the production frontier, the functional form, measurement of marginal products and measurement of factor substitution possibilities are discussed in this section.

### *Technical efficiency and production frontiers*

A sector's technical efficiency measures the ability to produce the maximum output possible from a given set of inputs and production technology. Technical efficiency is a relative concept since each sector's production performance is compared with a best-practice input–output relationship. The best-practice performance, or production frontier, is established by the practices of the most efficient sectors. Technical efficiency is then measured as the deviation of the individual sectors from this best-practice frontier.

This best practice is assumed stochastic, with a corresponding two-sided error term, to capture exogenous shocks beyond the control of firms. Since all sectors do not produce the frontier output, an additional one-sided error term is introduced to represent technical inefficiency. This approach contrasts with the production function which provides an average relationship between output and inputs over the entire sample, and in which a single, two-sided error term captures the stochastic influences and unobserved input usage.

The production frontier is estimated by stochastic frontier approach, which may be written (Aigner *et al.*, 1977) as

$$Y_i = h(X_1, X_2, \ldots, X_N, A)\, e^{\Phi_i} \tag{1}$$

where $Y_i$ is the output of the $i$th of the 47 sectors in the Bangladesh economy, $X_j$ is the $j$th of $N$ inputs, $A$ represents a vector of parameters, $e$ is the exponential operator, and $\Phi_i$ is a sector-specific error term. The error term $\Phi_i$ is composed of two independent components: $\Phi_i = V_i - U_i$. The systematic component, $V_i$, represents random variation in output due to factors outside the sector's control (such as weather), measurement error and statistical noise. It allows the deterministic production frontier to be stochastic. The technical efficiency relative to the stochastic frontier, $e^{-U_i} = Y_i/[h(X_1, X_2, \ldots, X_N, A)\, e^{-V_i}]$, is captured by the one-sided error component $U_i \geqslant 0$. When $U_i = 0$, production lies on the stochastic frontier and is technically efficient and, when $U_i > 0$, production lies below the frontier and is technically inefficient.

It is assumed that the symmetric error $V_i$ is independently and identically distributed as $N(0, \sigma_V^2)$ and that the non-negative error $U$ is distributed as the absolute value of a normal distribution, $|N(0, \sigma_U^2)|$, i.e. half-normal, and that $\sigma^2 = \sigma_U^2 + \sigma_V^2$. Define $\delta = \sigma_U/\sigma_V$. The greater $\delta$ is from unity, the more production is dominated by technical inefficiency, while the closer to zero, the more the discrepancy between the observed and frontier output is dominated by random factors beyond the control of the sector.

The inefficient component of $\Phi$ in the stochastic frontier, $U$, might be distributed other than half-normal. One possibility is the exponential distribution. A second possibility, proposed by Stevenson (1980), attempts to add an additional degree of flexibility to the one-sided error distribution. Stevenson proposed a truncated (at zero) normal distribution with non-zero mean for the distribution of $U$. This adds an additional parameter to the model, say $\mu$.

### *Translog production technology*

The production technology was specified as translog, which, following Berndt and Christensen (1973), can be written as

$$\ln Y = \alpha + \alpha_K \ln K + \alpha_L \ln L + \alpha_{KK} \ln K \ln K + \alpha_{KL} \ln K \ln L + \alpha_{LL} \ln L \ln L \tag{2}$$

where $Y$ represents output, $K$ is capital, and $L$ is labour. The translog production technology was interpreted as a second-order approximation to an underlying, unknown technology rather than as a direct representation of technology.

### *Marginal products*

Marginal products can be derived from the translog form. The logarithmic marginal product for capital may be written as

$$\delta \ln Y/\delta \ln K = (\delta Y/\delta K)/(K/Y) = \alpha_K + \alpha_{KK} \ln K + \alpha_{KL} \ln L.$$

Rearranging yields:

$$\delta Y/\delta K = [\alpha_K + \alpha_{KK} \ln K + \alpha_{KL} \ln L][K/Y].$$

Similarly, $\delta Y/\delta L = [\alpha_L + \alpha_{KL} \ln K + \alpha_{LL} \ln L][L/Y]$. A production function is usually considered to be well-behaved only if output increases monotonically with all inputs. Monotonicity holds if $\delta Y/\delta K > 0$ and $\delta Y/\delta L > 0$.

### *Elasticities of substitution*

From the translog production technology (Equation 2), one can compute the elasticity of substitution between inputs. Substitution elasticities are measured using Hicks' elasticity of complementarity (HEC) rather than the widely applied

Allen elasticity of substitution (AES) because of biases introduced in the latter when derived from a translog production function (Field 1988).[3] The cross HEC may be written as

$$h_{ij}=(\alpha_{ij}+M_iM_j)\ /M_iM_j \tag{3}$$

where $M_i$ is the logarithmic marginal product of factor $i$, $\ln(\delta Y/\delta X_i)$ . A positive (negative) value of $h_{ij}$ indicates that inputs $i$ and $j$ are $q$-complements ($q$-substitutes), so that increased usage of one increases (decreases) the usage of the other. With the Cobb–Douglas form, $\alpha_{ij}=0$ and $h_{ij}=1$.

The own HEC may be written as

$$h_{ii}=(\alpha_{ii}+M_i^2-M_i)\ /M_i^2 \tag{4}$$

Own HECs should be negative. Unlike the AESs, any maintained separability restrictions are directly imposed.

The HECs or AESs do not provide direct information on the behaviour of relative factor shares, but the direct elasticity of substitution (DES) and Morishima elasticity of substitution (MES) do (Sato and Koizumi, 1973; Blackorby and Russell, 1989; Kang and Brown, 1981). Because computation of the MES from the translog technology faces the same computational bias as the AES, attention has been restricted to the DES.

The DES measures the substitution between two inputs along an isoquant with all other inputs and output held constant. Following McFadden (1963), the DES between $X_i$ and $X_j$ is defined as

$$d_{ij}=[\mathrm{d}(X_i/X_j)/\mathrm{d}(f_i/f_j)][(X_i/X_j)/(f_i/f_j)] \tag{5}$$

where $f_i=\delta f(X)/\delta X_i$ and $i$ is not equal to $j$. The DES is a generalization of the two-factor elasticity of substitution formula applied to each pair and is symmetric. The DES lies between zero and infinity, and grows larger as the substitution becomes easier between two inputs. The DES is a two-factor, two-price elasticity of substitution. The DES is a short-run elasticity since it holds all other inputs constant, but under weak (or strong) separability (or only two inputs), the DES, a short-run measure, equals the long-run two-factor, two-price elasticity of substitution for the separable inputs (Mundlak, 1968).[4]

The DES for the translog production technology at the point of approximation may be written as (Boisvert, 1982)

$$d_{KL}=\frac{-[\alpha_K+\alpha_L]}{-[\alpha_K+\alpha_L]+\dfrac{\alpha_K^2\alpha_{LL}-2\alpha_K\alpha_L\alpha_{KL}+\alpha_L^2\alpha_{LL}}{\alpha_K\alpha_L}} \tag{8}$$

## III. ESTIMATION

In comparison to the maximum likelihood estimates of the frontier model, 'Ordinary least-squares estimates are inefficient and the estimate of the constant term is inconsistent (at least within the assumptions of the frontier model)' (Greene, 1990, p. 329). The differences between the average production function and the frontier should be intercept differences (Cowing *et al.*, 1988). This can be seen from $V_i$ in the frontier error term $V_i-U_i$. In the average function this would be absorbed in the constant term, shifting it neutrally downward, leaving the slope coefficients the same. However, the slope coefficients might also display statistically significant differences since the OLS estimates are inefficient (Greene, 1990).

However, as noted by Cowing *et al.* (1988), the statistical and the economic differences (e.g. elasticities, scale economies, marginal products) must be distinguished. In their own words, 'Even if frontier estimates are statistically different from the OLS estimates, it may be the case that such differences are of little economic importance. This question is of interest, for, ..., frontier estimation is considerably more difficult than least squares' (Cowing *et al.*, 1988, p. 65).

### *Model specification*

An industry-level production technology was estimated for 47 sectors of the Bangladesh economy during 1976–77.[5] The output $Y$ was defined as the sectoral outputs in millions of Taka. Two inputs per sector were specified: $K$ for capital in millions of Taka and $L$ for labour in thousands of man-years. As discussed above, the stochastic production frontier has an additive two-sided error term normally distributed and representing random disturbances. The other component represents deviations in technical efficiency. Three alternative specifications are evaluated: (1) half-normal (2) exponential and (3) the generalized form of Stevenson (1980). The production function is estimated with a single additive, normally distributed error term, which represents stochastic disturbances.

### *Nested hypothesis testing and final form of the technology*

The general translog form of the production technology in Equation 2 might not be the final form, which in turn has important implications for the elasticities of substitution, marginal products, and measures of economies of scale.

---

[3] Field (1988) notes that AESs estimated from the (primal) translog production function may not be desirable because the matrix of the estimated coefficients must be inverted to derive an AES. If one coefficient has a large standard error, all AESs are affected.

[4] Hence, the results for the separable inputs hold for both partial and full static equilibrium and any output level. In addition, the (symmetric) DES provides information on the relative shares of inputs $i$ and $j$, $S_i$ and $S_j$, where sign is $\delta(S_i/S_j)\ /\delta(X_i/X_j)\ >|=|<0$ according as $d_{ij}>|=|<1$ (Sato and Kazomi, 1973). Thus, if capital $K$ is substituted for labour $L$, so that the ratio of capital to labour increases, the share of capital increases/remains constant/decreases relative to the share of labour as $d_{KL}>|=|<1$.

[5] The existence of an aggregate production technology is assumed, which in turn requires the maintained hypothesis of additive separability among firms (van Daal and Merkies, 1984).

Restrictions on the production possibilities can be tested by a series of nested econometric restrictions on the production technology, Equation 2. The translog production technology might be characterized by CRTS or even the more restrictive Cobb–Douglas form. In the latter case, the technology is globally homogeneous, strongly separable in the inputs, and with constant unitary elasticities of substitution. In contrast, the technology with the translog form is not restricted to homogeneity and the elasticities of substitution are not *a priori* restricted constant or strongly separable in the inputs.

These hypothesis tests follow a nested sequential procedure, starting with a test for constant returns to scale and proceeding to tests for the Cobb–Douglas form and Cobb–Douglas with CRTS. Each succeeding hypothesis is tested given that the previous hypothesis is maintained. The testing procedure ends whenever a hypothesis is rejected. Following Denny and Fuss (1977), the overall significance of the nested hypothesis tests is approximately the sum of the individual test's significance. A significance of 0.025 is assigned for each test, giving an overall significance of 0.075. Because the translog function is interpreted as a second-order approximation to an underlying production technology, the tests hold only at the point of approximation and approximately in the neighbourhood of the point of expansion (Denny and Fuss, 1977).

CRTS requires the following econometric restrictions on the translog production function of Equation 2 (Berndt and Christensen, 1973):

$$\alpha_K+\alpha_L=1 \quad \text{and} \quad \alpha_{KK}+\alpha_{LL}+\alpha_{KL}=0 \tag{7}$$

The restriction for the Cobb–Douglas functional form is

$$\alpha_{KL}=0 \tag{8}$$

If the null hypothesis (Equation 8) is not rejected, homogeneity, strong separability and unitary elasticities of substitution among all inputs are maintained hypotheses. The restriction for constant returns to scale with Cobb–Douglas is (given $\alpha_{KL}=0$)

$$\alpha_K+\alpha_L=1 \tag{9}$$

### *The data*

The data used in this paper are taken from Alauddin (1986) and Alauddin and Tisdell (1988) and the 47-sector input–output table prepared by the Bangladesh Planning Commission (BPC, 1980a, b). The details of the sector classification scheme, the methodology of estimates and their limitations have been discussed elsewhere by Alauddin (1986) and Alauddin and Tisdell (1988) so we do not wish to repeat them here. Estimates of capital requirements were obtained by taking the product of the fixed capital coefficients for various industries and their corresponding output levels as reported by the Bangladesh Planning Commission (BPC 1980a, pp. 12–24). Depending on the sectors, these coefficients were estimated on three different bases, the details of which appear in BPC (1980a, p. 24). Clearly, the estimates involve conjectures and may not be entirely reliable and, therefore, they may have serious limitations for policy purposes. It is well-known that many conceptual difficulties and statistical pitfalls surround the estimation of capital stock (see, for example, Harcourt, 1973). Nevertheless, given that the primary objective of the paper is to illustrate how there can be a divergence between average and frontier production technology estimates using the same data base, the accuracy of the data estimates can be considered to be of secondary importance.

Note that the data, since they relate to the year 1976–77, are quite old. Although a 53-sector input–output table for a later year, 1981–82, is available (BPC, 1990), the employment series for that particular year is not yet available. The 1981–82 data could not be used for this analysis. Fortunately, the 1976–77 data still enable the main methodological issues to be investigated empirically.

### *Econometric estimation*

Econometric estimation of the frontier form of the translog production technology given in Equation 2 used maximum likelihood under the behavioural assumption of the expected profit maximization for the three distributions of $U_i$.[6] Symmetry of the second-order coefficients follows from Young's theorem on the order of differentiation of a continuous function, and the symmetry is imposed as a maintained hypothesis in Equation 2, giving: $\alpha_{KL}=\alpha_{LK}$.

Estimation of the standard translog production function given in Equation 2 was by OLS under the hypothesis of the expected profit maximization. The $R^2$ was 0.855, indicating a good fit for the cross-sectional data. The Lagrange multiplier test of Breusch and Pagan (1979) for a null hypothesis of heteroscedasticity of the form Var $[\varepsilon]=h(\beta'X)$ gave a chi-square test statistic of 6.422 with five degrees of freedom, thereby not rejecting the null hypothesis at the conventional levels of significance.[7] As a consequence, White's (White,

---

[6] Zellner *et al.* (1966) showed that a direct estimation of the primal production technology without this behavioural assumption gives biased and inconsistent estimates because of simultaneity between inputs and output. Under the behavioural assumption of the expected profit maximization, inputs may be assumed exogenous rather than endogenous.

[7] Interpreting the production technology as a second-order approximation, rather than as a direct representation, of technology and use of an additive error term introduces heteroscedasticity because the remainder term of the second-order Taylor series approximation is incorporated into the residuals (Kulatilaka, 1987). In addition, the use of data aggregated by arithmetic means can also introduce heteroscedasticity. Heteroscedasticity is also often found in cross-sectional data. Hence, a very general form of heteroscedasticity from a number of sources is allowed .

Table 1. *Nested hypothesis tests for final form of production technology*

| | Chi-square or $F$-test | | | |
|---|---|---|---|---|
| | Stochastic production frontier | | | |
| Hypothesis test | Half-normal | Exponential | Generalized | Production function |
| CRTS translog | 193.225 (2) | 194.340 (2) | 144.877 (2) | 1.2941 (2,41) |
| Cobb–Douglas functional form | | | | 4.402 (3,41) |
| CRTS Cobb–Douglas form | | | | 206.60 (1,44) |

Note: Wald test for production frontier and $F$-test for production function. Level of significance for each individual test is 0.025 and overall significance is 0.075. Degrees of freedom in parenthesis.

1980) procedure was applied to obtain heteroscedastic-consistent estimates of the parameters.[8]

A direct estimation of the production technology, under the hypothesis of the expected profit maximization, was elected rather than the estimation of the production technology and its first-order conditions (less one), since the latter approach requires constant returns to scale for the cost shares to sum to unity and thereby avoid singularity of the variance–covariance matrix of residuals. Moreover, estimation of Equation 2 with its first-order conditions without scaling of the data by sample means (to maintain consistency between the production frontier and production function) places the residuals from the objective function and the first-order conditions on the same measurement scale. Finally, estimation with cross-sectional, rather than time-series, data and with the small number of explanatory variables should minimize any multicollinearity that might arise from the direct estimation rather than the systems approach of Equation 2 and its first-order condition.[9]

### *Final form of the production technology*

The results of the nested hypothesis testing for the final form of the production technology for the production frontiers and production function are summarized in Table 1. The overall level of significance for each nested testing sequence was 0.075, while the level of significance for each test within each nested testing sequence was 0.025. The three production frontiers are considered first and then the production function. Wald tests (Godfrey, 1988) were used for the production frontiers and $F$-tests were used for the production function. The Wald test is distributed as chi-square with degrees of freedom equal to the number of independent restrictions.

The Wald test rejected the null hypothesis of constant returns to scale in all the specifications of the stochastic frontier. Because the testing is nested, it was terminated at this point. In sum, the unrestricted translog frontier was not rejected at an overall level of significance of 0.075 (and lower) as the final form of the frontier. The parameter estimates are reported in Table 2.

The null hypothesis of CRTS for the translog production function was not rejected at both the 0.025 and 0.01 levels of significance, since the $F$-statistic was $F(2, 41) = 1.2941$, with numerator and denominator degrees of freedom in parenthesis. The null hypothesis of Cobb–Douglas functional form for the production function was rejected at a 0.025 level of significance by an $F$-test with $F(3, 41) = 4.402$, but was marginally rejected at 0.01 significance. The null hypothesis of CRTS for the Cobb–Douglas production function was rejected. The Breusch–Pagan test for heteroscedasticity gave a chi-square test statistic with two degrees of freedom of 47.2501, decidedly rejecting the null hypothesis of no heteroscedasticity. The estimates were corrected for heteroscedasticity (heteroscedastic-consistent estimates), following White (1980).

## IV. COMPARISON OF PRODUCTION TECHNOLOGY

The nested hypothesis tests for the final forms of the stochastic production frontiers and production function indicated that, at the 0.075 level of overall significance, both representations of production possibilities were translog, with the production function displaying CRTS. Moreover, there was an indication that, at a lower level of overall significance, the final form of the production function would be Cobb–Douglas.

---

[8] Heteroscedasticity of the production *frontier* cannot be tested by the Breusch–Pagan test and corrected with current econometric packages. Hence, it is not known if the frontier's parameter estimates are heteroscedastic or not and the parameter estimates of the *frontier* function are not necessarily heteroscedastic-consistent.

[9] The condition index detects multicollinearity and is the square root of the ratio of the largest to the smallest characteristic root of $X'X$, where $X$ is the vector of regressors (Belsley *et al.*, 1980). The computed value of 0.0159 indicates that multicollinearity does not pose a serious problem.

Table 2. *Parameter estimates of production technology*

| | Production function | | | Stochastic frontier | | |
|---|---|---|---|---|---|---|
| Variable | Cobb–Douglas | Unrestricted translog | CRTS translog | Half-normal | Exponential | Generalized likelihood |
| Intercept | 3.793* | 1.989* | 2.776* | 2.317* | 2.147* | 2.261 |
| | (0.868) | (0.391) | (0.146) | (0.682) | (0.685) | (13.804) |

| $\mu$ | | | | | | 0.0002 |
| | | | | | | (63.259) |
| Log-likelihood | | | | −39.919 | −39.893 | −40.111 |

Note: Translog functional form unless otherwise stated. Standard errors in parentheses. Heteroscedastic-consistent estimates for standard production function.
*Denotes significance at 5% level.

### *Statistical tests for equality of coefficients*

A direct comparison of parameter estimates for the translog production function and the stochastic production frontier reported in Table 2 indicates fairly close similarity between the intercepts and first-order and second-order coefficients.[10]

As discussed above, the differences between the stochastic production frontier and the production function should be intercept differences, so that the stochastic frontiers and production function merely represent neutral shifts from one another. The slope coefficients, however, might display statistically significant differences due to the inefficient estimates of OLS. Following Cowing *et al.* (1988), statistical tests of these differences were conducted. An $F$-test on the null hypothesis that all coefficients except the intercept are the same in the stochastic frontiers was first run against both the unrestricted and CRTS translog production functions as the null. The estimated $F$ for the unrestricted (CRTS) translog production function as the null was: (1) $F(5,41)=0.2043$ (3.836), for the half-normal; (2) $F(5,41)=0.2040$ (3.938) for the exponential; and (3) $F(5,41)=0.5639$ (3.813) for the generalized likelihood, indicating no statistically significant difference. The null hypothesis that all intercept coefficients were the same in both models was tested by a Wald test with the stochastic frontier as the null. The chi-square statistic of the Wald test with five independent restrictions for the unrestricted (CRTS) translog production function gave a value of: (1) 23.0505 (467.402) for the half-normal; (2) 23.005 (470.848) for the exponential; and (3) 0.042598 (456.161) for the generalized likelihood, rejecting the null hypothesis for the half-normal and exponential forms but not for the generalized likelihood with the unrestricted translog production function and uniform rejection for the CRTS translog production function.

The second-order coefficients play a crucial role in flexible functional forms, giving them their 'flexibility'. Test of significance for the null hypothesis of no differences in the second-order coefficients against the unrestricted (CRTS) translog production function as the null gave: (1) $F(3,41)=0.0002$ (2.905) for the half-normal; (2) $F(3,41)=0.0003$ (2.980) for the exponential; and (3) $F(3,41)=0.0002$ (3.058) for the generalized likelihood, all implying no differences for the unrestricted translog but differences for the CRTS translog. The Wald test of no differences in the second-order coefficients against the stochastic frontier as the null gave chi-squares with three degrees of freedom for the unrestricted (CRTS) translog of: (1) 269.165 (14.903); (2) 399.00 (15.456) and (3) 292.008 (14.142), respectively, for the half-normal, the exponential and the generalized likelihood, rejecting the null hypothesis of no differences for both the unrestricted and CRTS translog production function.

---

[10] We may have omitted variable bias in the estimated coefficients, since land and human capital, the omitted variables, are likely to be correlated with the included variables.

Table 3. *Hicks elasticities of complementarity*

| | Production function | | | Stochastic frontier | | |
|---|---|---|---|---|---|---|
| Variable | Cobb–Douglas | Unrestricted translog | CRTS translog | Half-normal | Exponential | Generalized likelihood |
| Capital | −2.696 | −0.264 | −0.196 | −0.250 | −0.257 | −0.264 |
| Labour | −1.258 | −0.549 | −0.207 | −0.630 | −0.563 | −0.550 |
| Capital–labour | 1 | 0.825 | 0.337 | 0.822 | 0.823 | 0.825 |

Note: Calculated at point of approximation.

Table 4. *Direct elasticities of substitution*

| | Production function | | | Stochastic frontier | | |
|---|---|---|---|---|---|---|
| Variable | Cobb–Douglas | Unrestricted translog | CRTS translog | Half-normal | Exponential | Generalized likelihood |
| Capital–labour | 1.000 | 1.207 | 8.078 | 1.294 | 1.211 | 1.207 |

Note: Calculated at point of approximation.

In sum, mixed information was found on the statistical differences between the coefficients of the production function and the three stochastic frontiers.

### *Economic differences*

Since parameter estimates from second-order functional forms, whether interpreted as direct or second-order approximations of technology, have little meaning in themselves, the factor substitution possibilities, marginal products and scale economies are examined next in order to make more meaningful comparisons about the production technology and implications for economic policy formation. The elasticities were evaluated at the point of approximation.

The Hicks elasticities of complementarity (HEC) for the translog form are reported in Table 3. The HECs are negative for both the production frontiers and the production function, as expected for a well-behaved production technology. The own HECs are inelastic for both the production frontiers and translog production function, with the production function having slightly larger absolute values for own HECs. The HECs for the CRTS translog production function were more inelastic than the unrestricted translog or Cobb–Douglas forms. The HECs between capital and labour indicated inelastic *q*-complementarity, so that increased usage of one increases the demand or marginal product of the other. Complementarity among inputs, or 'cooperant' factors, is generally expected to prevail (Hicks, 1946; Sakai, 1974). Policy formation based upon an accurate measurement of the cross HEC should give similar results (unless the production function is interpreted as Cobb–Douglas, where $\mathrm{HEC}_{KL}=1$).

The direct elasticities of substitution (DES) for capital and labour are reported in Table 4. The DESs for the production frontier and the production function are all around 1.207, except for the CRTS translog production function, which has a DES of 8.078. Hence, the capital–labour isoquants for the production frontiers and unrestricted translog production function are similar and are more elastic and flatter in shape than that for the Cobb–Douglas form and the CRTS translog production function's DES is considerably more elastic than any other. Moreover, if capital $K$ is substituted for labour $L$, so that the ratio of capital to labour increases, the share of capital will increase relative to the share of labour for both the production frontiers and function if the latter is interpreted as translog. If the production function is Cobb–Douglas, then the income shares are constant. In sum, policy targeting income distribution and relative factor shares could provide very dissimilar results, depending upon the specification of technology.

The marginal products for the production frontiers and the production function are reported in Table 5. They are calculated for mean values of capital, labour and output. They are all positive, indicating that the monotonicity condition of a well-behaved production technology is satisfied. In this case, marginal products for the production frontiers and the production function are virtually the same. Hence, policies requiring knowledge of marginal products, such as those targeting allocative efficiency, would provide virtually identical results.

Economies of scale can be measured as the sum of the production coefficients: $\delta \ln Y/\delta \ln K+\delta \ln Y/\delta \ln L$. At the point of approximation, this measure becomes simply $\alpha_K+\alpha_L$. This value is 1.386, 1.388 and 1.389, respectively, for the half-normal, exponential and generalized production

Table 5. *Marginal products*

| | Production function | | | Stochastic frontier | | |
|---|---|---|---|---|---|---|
| Variable | Cobb–Douglas | Unrestricted translog | CRTS translog | Half-normal | Exponential | Generalized likelihood |
| Capital | 0.355 | 1.126 | 1.196 | 1.138 | 1.133 | 1.126 |
| Labour | 0.027 | 0.056 | 0.013 | 0.057 | 0.858 | 0.058 |

Note: Calculated at point of approximation.

frontiers, is 1.389 and 1.000 for the unrestricted and CRTS translog production functions, respectively, and 0.714 for the Cobb–Douglas. Hence, economic policies targeting scale economies would be affected by the specification of the production technology.

### *Fitted values*

The fitted values from the translog stochastic frontiers and the translog production function should match one another if the two give equivalent representations of technology. The fitted values were regressed from the unrestricted translog production function upon those of the stochastic frontier with the half-normal error term in the relationship $Y=\alpha+\beta X$ to evaluate slope intercept differences between the two series. Ideally, the intercept should be zero and the slope unity if the two data series are the same. The results of the regressions were:

| | coefficient | $t$-ratio |
|---|---|---|
| $\alpha$ | $-0.0179$ | $-2.060$ |
| $\beta$ | 1.0024 | 723.549 |

with $R^2=0.999941$. The intercept $\alpha$ clearly differs from zero given the $t$-ratio of $-2.060$. This result is expected if the intercepts between the translog stochastic frontiers and production function are different due to the technical inefficiency term $U_i$ in the stochastic frontier's disturbance term. The $F$-test on the linear restriction that the slope is unity, i.e. $\beta=1$, gave the result $F(1, 45)=4.4782$, marginally rejecting the null hypothesis that $\beta=1$ at 0.05 but not at 0.025 or 0.001. In sum, there will be systematic, statistically significant differences between the two due to the disturbance term, affecting the intercepts, and possibly the slope coefficients.

### *Nested and non-nested tests*

The relationship between the unrestricted translog stochastic frontiers and unrestricted translog production function can be tested formally. The production function can be viewed as a restricted version of the stochastic frontier through the error term $\Phi_i=V_i-U_i$. The econometric restriction is $\delta=\sigma_u/\sigma_v=1$. Hence, as inefficiency becomes insignificantly small, the frontiers' probability density functions become indistinguishable from the normal for $U_i$ distributed half-normal, exponential or following the generalized likelihood. The estimated values of $\delta$ are: (1) $\delta=0.646$ with a standard error of 2.242 for the half-normal; (2) $\delta=0.5977$ with a standard error of 5.784 for the generalized likelihood; and (3) $\delta=6.196$ with a standard error of 20.312 for the exponential. The results indicate that there are no statistical differences between the different translog stochastic frontiers and unrestricted translog production function estimated by OLS.

The test on $\delta$ and on the equality of coefficients specifies the alternative to the null and contains the null as a special case. Hence, this is a nested specification test. When the alternative is fully specified but does not contain the null model as a special case, specification tests are known as non-nested or encompassing hypotheses (Godfrey, 1988).

These non-nested tests can be applied to the translog stochastic frontier and the unrestricted translog production function as a check that a systematic but unknown difference does not exist. The MacKinnon et al. extension (MacKinnon *et al.*, 1983) of the $J$-test (Davidson and MacKinnon, 1981) was applied. The $t$-ratio for the test against the stochastic frontier as the null was 0.606 and the log-likelihood was $-39.826$. The $t$-ratio for the test against the unrestricted translog production function as the null was $-0.340$ and the log-likelihood was $-39.816$. The results lend weight to the conclusion that there are no statistical differences between the two unrestricted translog models.

## V. CONCLUDING REMARKS

It has been shown that depending on the method of hypothesis testing and the initial null hypotheses chosen, significant differences or no differences between the estimated average production function and the stochastic production frontier and various functional forms may be observed. Because of these the following procedures are suggested.

It may be preferable to first begin any analysis of production technologies with nested hypothesis testing of technical inefficiency and non-nested hypothesis testing for systematic but unknown differences between the unrestricted forms of the average and frontier production functions. Nested specification tests on the final form of the production technology would follow after first selecting between the average and stochastic frontier functions.[11] This hypothesis testing sequence starts from the most general question, that of the average or stochastic frontier representation of technology, and proceeds to specific forms for the selected representation of technology (average or frontier). While this sequence is not formally and explicitly nested, it does proceed from the most general to the most specific.[12] Alternatively, beginning hypothesis testing for the final form of the technology could give misleading results without first testing between the average and stochastic frontier functions. In turn, economic policy formation, such as that based on relative income shares, factor substitution possibilities, and technical efficiency differentials could differ.

For the Bangladesh data, nested hypothesis tests on the final form of the production technology indicated a significant difference between the average production function and stochastic production frontier; the average production function was CRTS translog and possibly even Cobb–Douglas and all three stochastic frontiers were unrestricted translog. In contrast, nested hypothesis tests of technical inefficiency and non-nested hypothesis testing for systematic but unknown differences indicated no significant differences. Certainly, for the Bangladesh data we examined, economic policy could have built inappropriately upon a translog stochastic production frontier rather than the appropriate CRTS translog or perhaps Cobb–Douglas average production function. In this case, there is little scope for policies to improve management efficiency by ensuring that all sectors adopt frontier management practices, since these practices are already being adopted and deviations are due to random factors.

The frequency of divergent results, such as those obtained on the basis of the Bangladesh data, is difficult to anticipate *a priori*. Instead, it seems to be an empirical issue, which must be examined on a case-by-case basis.

## ACKNOWLEDGEMENTS

We wish to acknowledge the helpful suggestions made by an anonymous referee of this journal on an earlier draft of this paper. Squires is grateful for support from the Department of Economics, University of Queensland, where most of this work was completed while a visitor. ---

[11] Selection of the average production function and estimation by OLS would not imply inefficient estimates in comparison to the frontier model, since that inefficiency is predicated on a distinguishable difference between the two models.

[12] The tests of technology and pooling would not be nested as a group. Hence, the statistical significance of the tests would not be the (approximate) sum of the individual tests' significances (cf. Denny and Fuss, 1977). However, Godfrey (1988) notes that when there is a high degree of dependence between the individual significance tests, the actual overall significance level may be somewhat smaller than its upper bound of $s\alpha$, where $s$ is the number of tests and $\alpha$ is the significance level of each test.

# Testosterone response to a gonadotrophin-releasing hormone agonist in Hawaiian monk seals (*Monachus schauinslandi*)

S. Atkinson[1], W. G. Gilmartin[2] and B. L. Lasley[3]

[1]*Hawaii Institute of Marine Biology, University of Hawaii, 1000 Pope Road, Marine Science Building 212, Honolulu, HI 96822, USA;* [2]*Honolulu Laboratory, Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA, 2570 Dole Street, Honolulu, HI 96822-2396, USA; and* [3]*Department of Reproduction, School of Veterinary Medicine, University of California, Davis, CA 95616, USA*

Adult male Hawaiian monk seals were administered a gonadotrophin-releasing hormone (GnRH) agonist to determine its effectiveness in reducing the testicular production of testosterone. Blood samples were collected from four treated seals and two control seals at weekly intervals for 10 weeks and again at the beginning of the following breeding season. The GnRH-agonist had an initial, brief, stimulating effect on circulating testosterone, but this was followed by an inhibitory effect that lasted for 7 to 8 weeks. The plasma concentrations of testosterone were within normal ranges by the following spring. These results demonstrate a reversible form of long-term androgen suppression, which may have applicability in a variety of wildlife management programmes.

## Introduction

The Hawaiian monk seal (*Monachus schauinslandi*) was listed as 'endangered' in 1976 after a 50% reduction in the number of seals observed in beach counts over 20 years (Johnson *et al.*, 1982). In addition to the reduction in the number of animals, three of five major breeding populations also showed an imbalance in the adult sex ratio. Although the cause and chronological development of this condition remain uncertain, by the early 1980s, when extensive monitoring of the population began, male Hawaiian monk seals outnumbered females by at least 2:1 at Laysan Island (Johnson and Johnson, 1981), Lisianski Island (Stone, 1984) and Kure Atoll (Gilmartin, *et al.*, 1986). The disparate sex ratio at Kure Atoll was resolved by management actions which included introducing females and enhancing survival of young females (Gerrodette and Gilmartin, 1990; Van Toorenburg *et al.*, in press).

The skewed adult sex ratio still exists at Laysan and Lisianski Islands and it is associated with anomalous breeding behaviour termed 'mobbing'. Mobbings are mass matings wherein groups of males (4–14 or more) attempt copulation with a female or with an immature seal of either sex. Mobbing events have been observed to last several hours and usually result in severe injury and often death of the adult female or immature seal, either directly from the injury or indirectly by shark attack (Johnson and Johnson, 1981; Johanos and Kam, 1986; Alcorn and Buelna, 1989). The differential mortality between the adult sexes owing to mobbing attacks appears to be a major factor in maintaining these skewed sex ratios in adults and perpetuating mobbing incidents.

The Hawaiian monk seal is a seasonal breeder (Kenyon and Rice, 1959; Atkinson and Gilmartin, 1992) and mobbing attacks by adult males occur during the height of the breeding season, from May to July (L. M. Hiruki and W. G. Gilmartin, unpublished), when most females have weaned their pups and are thought to be resuming ovarian activity. This period correlates with the annual peak in circulating testosterone in males (Atkinson and Gilmartin, 1992).

Gonadotrophin-releasing hormone (GnRH) agonists have been used in humans to suppress secretion of testicular androgen to reduce the probability of metastasis of androgen-dependent prostate carcinomas (Parmar *et al.*, 1985). Similarly, GnRH agonists have been shown to suppress androgen production in dogs (Sandow *et al.*, 1980), monkeys (Sundaram *et al.*, 1982) and rodents (Redding *et al.*, 1984), with an attendant decrease of libido in dogs (Sandow *et al.*, 1980). However, reduction of testosterone production alone, via castration, does not always reduce androgen-mediated behaviour in dogs (Le Boeuf, 1970). In the harbour seal (*Phoca vitulina*) testosterone reduction by GnRH agonist has been shown to correlate with a reduction in sociosexual behaviour (Yochem *et al.*, 1991). Thus, we hypothesized that treatment of Hawaiian monk seals with a GnRH agonist would suppress testicular production of testosterone. The research reported herein was designed to test this hypothesis in captive adult male monk seals and, if an effect was detected, to measure the duration of testosterone suppression.

## Materials and Methods

### *Animals and treatments*

Five captive adult male Hawaiian monk seals, housed at Sea Life Park and Waikiki Aquarium, Oahu, Hawaii, were used for this trial. All of the male seals were at least 10 years old and annual veterinary physical examinations suggested that they

Received 3 December 1991.

© 1993 Journals of Reproduction and Fertility Ltd

were in good health. No adult females were present in the enclosures at either site. In June 1990, during the natural breeding season and when secretion of testosterone was at its highest (Atkinson and Gilmartin, 1992), three of the five seals (A, N and P) were given 11.25 mg of a GnRH-agonist, D-Trp6-luteinizing-hormone-releasing hormone (LHRH) (Decapeptyl-CR: Ferring, NY). The dose was determined by multiplying the human dose (3.75 mg) by 3, to approximate an equivalent dose for the seals who weighed about 200 kg. Seals S and Z were not given the drug at this time, but were handled and sampled at the same frequency as the test animals. The GnRH agonist was injected i.m. at three sites in the pelvic area of each of the treated seals. Blood samples were collected before treatment with the agonist and then weekly from all five seals for 10 weeks after the GnRH agonist was administered. The blood sampling procedure has been described (Atkinson and Gilmartin, 1992). Plasma from these samples was stored frozen at −20°C until radioimmunoassay for testosterone could be performed. Four weeks after the first three seals were injected, one of the control seals, animal Z, was given 5.6 mg of the GnRH agonist. Blood sampling for this animal was continued for 8 weeks. Early in the following breeding season, 9 months after the GnRH was given, an additional blood sample was collected from each seal.

### *Hormone measurement*

Testosterone was measured in the plasma with a single antibody radioimmunoassay (Atkinson *et al.*, 1986; Atkinson and Gilmartin, 1992). All oestrogen and progesterone compounds had $< 1\%$ crossreactivity (Atkinson *et al.*, 1986). Crossreactivity with dihydrotestosterone, 4-androstene-3β,17β-diol and androstenedione was 98, 47 and 4.7%, respectively, thus measuring the majority of circulating androgens. Nonspecific binding of the antibody was $< 5\%$, and the sensitivity of the assay was 0.03 ng per tube. Extraction recovery was 88.1%. A pool of monk seal plasma containing $2.06 \pm 0.18$ ng testosterone $\mathrm{ml}^{-1}$ plasma was included in each assay to determine interassay variation, which was $< 15\%$.

### *Statistical analysis*

Log–logit transformations were applied to the standard curve of the assay (Rodbard, 1974). Student's *t* test was used to compare the differences in hormone concentrations before and after injection.

## Results

Two of the three seals, P and N, injected with 11.25 mg GnRH agonist, and seal Z, injected with 5.6 mg, showed transient increases in circulating testosterone 1 week after the injection (Fig. 1). Within 2 weeks of the injections, the plasma concentration of testosterone in all seals had fallen significantly ($P < 0.001$) and remained at similar values to that in castrated animals for 7 to 8 weeks. Between 9 and 10 weeks after the injection, testosterone concentrations in seals A, P and N began to rise (Fig. 1a–c). Testosterone concentrations in seal Z also increased, although the sampling frequency was reduced. The control seal (S) maintained high and relatively constant plasma testosterone concentrations throughout the study (Fig. 1e), while being exposed to the same sampling stress as the experimental protocol. Early in the following breeding season, the mean testosterone concentrations of the treated seals ($0.52 \pm 0.08$ ng $\mathrm{ml}^{-1}$) were similar to that of the control seal (S: 0.60 ng $\mathrm{ml}^{-1}$).

## Discussion

This study demonstrated that an injection of a GnRH agonist can be used to reduce circulating testosterone concentrations of Hawaiian monk seals for about 2 months. The GnRH agonist used in this study (D-Trp6-LHRH) is a potent synthetic LHRH analogue which differs from the naturally occurring LHRH in that the glycine in amino acid position 6 has been replaced by D-tryptophan. This replacement leads to enhancement of the affinity for the LHRH receptors in the pituitary and a longer than normal half-life of the analogue. GnRH agonists initially stimulate the anterior pituitary to produce increased amounts of luteinizing hormone (LH). This was apparent in three of the four seals injected in the present study. While the increase was variable in the animals, we suspect that this was due to the sampling interval and recognize the need to characterize this transient increase with more frequent sampling.

Large doses (Sundaram *et al.*, 1982) or chronic administration of GnRH agonists (Bergquist *et al.*, 1979) have the paradoxical effect of decreasing LH, which leads to a decrease in the production and secretion of gonadal steroids. This decrease in the pituitary response is thought to reflect a desensitization of the pituitary or a refractory phase, accompanied by the down-regulation of local LH receptors (Sundaram *et al.*, 1982). The decreased testosterone is probably due to a decrease in the concentrations of 17,20-desmolase and 17α-hydroxylase in the Leydig cells, leading to a block in the steroidogenic pathway to testosterone synthesis (Chasalow *et al.*, 1979).

All but one dose used in the present study were scaled on a body weight basis from the dose recommended for treatment of male humans with androgen-dependent prostate carcinomas. One seal in the study received 5.6 mg of the GnRH agonist, which is half the dose of the other three treated seals. This half dose resulted in the same reduction in plasma testosterone observed in A, N and P, suggesting that the dose administered to these seals was well above the threshold required to achieve the desired response.

The concentrations of testosterone at the start of the study were similar for all animals except for seal A. Although the testosterone concentration appeared high in seal A, it was within the normal range of captive and wild seals sampled to date (Atkinson and Gilmartin, 1992).

This study was undertaken as a preliminary assessment leading to use of a GnRH agonist as an agent to control aggressive sociosexual behaviour, mobbing, in Hawaiian monk seals in the wild. While the animals in this study were housed in naturalistic enclosures, they were not exposed to adult female monk seals. Thus, it was not possible to assess the effects of the treatment on libido or aggressive behaviour, which exist in the wild during the breeding season when oestrous female seals are available.

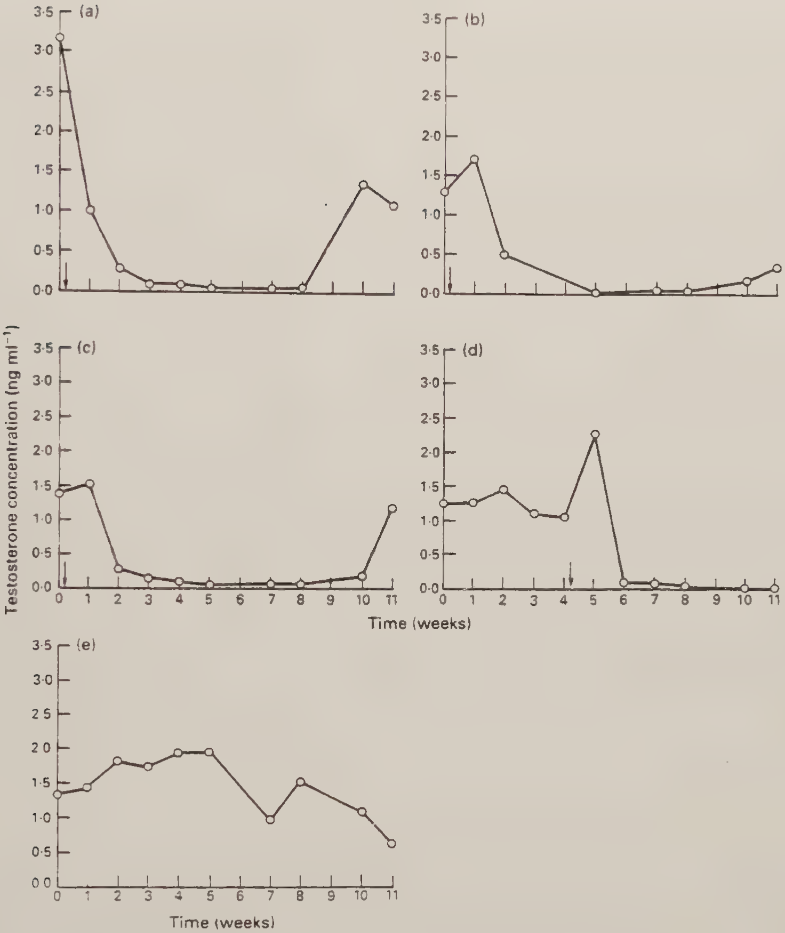

**Fig. 1.** Testosterone concentrations in the plasma of male Hawaiian monk seals injected with D-Trpo-luteinizing-hormone-releasing hormone (LHRH): 11.25 mg for seals (a) A, (b) P and (c) N and (d) 5.6 mg for seal Z. The arrow marks the time of injection. (d) Seal Z served as a control prior to administration of D-Trp6-LHRH at week 4. (e) Seal S served as a control throughout the experiment.

GnRH agonists have various effects on fertility, depending on the species. Dogs (Sandow *et al.*, 1980) appear to be more sensitive to the antigonadal effects of GnRH agonists than are primates (Sundaram *et al.*, 1982) or rats (Chasalow *et al.*, 1979). Sperm production and quality were not measured in the present study; however, the plasma testosterone concentrations of the treated seals did return to the normal breeding season concentrations (Atkinson and Gilmartin, 1992) by the following season, indicating that any effects on fertility were probably reversible. The effects on fertility are an obvious consideration that should be assessed, if restoration of breeding ability is deemed critical, before such treatments are used for behaviour modification in wildlife management programmes.

The GnRH agonist tested, D-Trp6-LHRH, demonstrated the ability to control production of testicular androgen in monk seals for about 2 months. Use of a repeated dose of this agent at 2 month intervals should allow suppression of testosterone for longer periods, increasing the probability that aggressive sexual behaviour in adult male Hawaiian monk seals may be controlled and the number of mobbing attacks reduced.

We thank M. Breese and her staff at Sea Life Park and C. Vanderlip and her staff at Waikiki Aquarium for help in animal handling; the Protected Species Investigation staff of the Honolulu Laboratory for help with logistics and sample collection; R. I. Cox and M. S. F. Wong for donation of testosterone antisera; M. Atkinson, G. Grau and P. Helfrich for the use of facilities at Hawaii Institute of Marine Biology; J. Pietraszek for preparing the figures; and B. Becker and T. Johanos-Kam for helpful discussions throughout this study. This project was funded in part by NOAA, Sea Grant College Program and Hawaii Institute of Marine Biology, University of Hawaii.

# Sulphide tolerance and adaptation in the California killifish, *Fundulus parvipinnis*, a salt marsh resident

T. BAGARINAO* AND R. D. VETTER†
*Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA 92093-0202, U.S.A.*

(*Received 19 March 1992, Accepted 29 August 1992*)

Hydrogen sulphide is a toxicant naturally produced in hypoxic marine sediments, hydrocarbon and brine seeps and hydrothermal vents. The California killifish, a salt marsh resident, is remarkably tolerant of sulphide. The 50% lethal concentration is 700 μM total sulphide in 96 h, and 5 mM in 8 h (determined in flow-through, oxygenated sea water). Killifish exposed to sulphide produce thiosulphate which accumulates in the blood. The cytochrome *c* oxidase (a major site of toxicity) of the killifish is 50% inhibited by $<1$ μM sulphide. Killifish liver mitochondria are poisoned by 50–75 μM sulphide but can oxidize 10–20 μM sulphide to thiosulphate. Sulphide causes sulphhaemoglobin formation (and impairment of oxygen transport) at 1–5 mM *in vitro* and to a small extent at 2 mM *in vivo*. Killifish blood neither catalyses sulphide oxidation significantly nor binds sulphide at environmental (low) sulphide concentrations. Exposure to 200 μM and 700 μM sulphide over several days causes significant increases in lactate concentrations, indicating shift to anaerobic glycolysis. However, individuals with the most lactate die. In terms of diffusible $H_2S$, the killifish can withstand concentrations two to three orders of magnitude greater than would poison cytochrome *c* oxidase. The high sulphide tolerance of the killifish, particularly of concentrations typical of salt marshes, can be explained chiefly by mitochondrial sulphide oxidation. Sulphide tolerance and mitochondrial sulphide oxidation in the killifish have a constitutive basis, i.e. do not diminish in fish held in the laboratory in sulphide-free water for 1–2 months, and are improved by prior acclimation.

Key words: *Fundulus parvipinnis*; sulphide tolerance and detoxication.

## I. INTRODUCTION

Sulphide is an important environmental factor and toxicant for aquatic plants, invertebrates and fishes (Theede *et al.*, 1969; Smith & Oseid, 1974; Ingold & Havill, 1984; Bagarinao & Vetter, 1989; Levitt & Arp, 1991; Bagarinao, 1992). In the marine environment, sulphide is produced mostly from bacterial sulphate reduction in sediments (Fenchel & Riedl, 1970; Jorgensen, 1984). Salt marshes, enclosed bays and estuaries and areas of pollution such as sewage outfalls are characterized by micromolar to millimolar sulphide concentrations in sediments (Bagarinao, 1992, for table of measured values). Effects of sulphide on various enzymes, cellular structures and physiological functions are well documented in the biomedical literature (National Research Council, 1979; Beauchamp *et al.*, 1984; Bagarinao, 1992). The major biochemical lesion caused by sulphide appears to be the inhibition of cytochrome *c* oxidase, the terminal enzyme in the electron transport chain of mitochondria. Another quite colourful effect of

sulphide is the formation of sulphhaemoglobin, a green derivative with a much reduced affinity for oxygen and therefore non-functional in oxygen transport (Carrico *et al.*, 1978*a*, 1978*b*).

Many species of fish spend all or part of their lives in shallow waters and may experience sulphide. Mass fish kills in dredged or impounded salt marshes, or in earthen culture ponds are often attributed routinely to hypoxia/anoxia, salinity and temperature fluctuations, or low pH (Waggoner & Feldmeth, 1971; Inland Fisheries Project, 1974), but it is quite likely that sulphide is responsible for some fish kills (Torrans & Clemens, 1982). Fishes also occur in the sulphidic water column of the Cariaco Trench (Baird *et al.*, 1973), at the deep-sea hydrothermal vents (Cohen & Haedrich, 1983; Rosenblatt & Cohen, 1986; Cohen *et al.*, 1990; Geistdoerfer, 1991), and hydrocarbon and brine seeps (Brooks *et al.*, 1979; Kennicutt *et al.*, 1985). Yet, sulphide has been almost totally overlooked as an environmental factor for marine fishes, except for our work.

The California killifish, *Fundulus parvipinnis* Girard, is a small, ecologically and physiologically versatile cyprinodontiform that spends its entire life in bays, lagoons and salt marshes from Morro Bay southward to Magdalena Bay in Baja California (Fritz, 1975; Allen, 1982). Earlier comparative studies have shown that the killifish is more tolerant to sulphide than several other species of shallow-water marine fishes (Bagarinao & Vetter, 1989), has remarkable sulphide-oxidizing activity in the mitochondria (Bagarinao & Vetter, 1990), but negligible sulphide-oxidizing and sulphide-binding capacity in the blood under physiological conditions (Bagarinao & Vetter, 1992).

This paper will present a model of sulphide tolerance in the California killifish, based on several sets of data, most of which are presented here, and some already published. The specific questions addressed are:

(i) How much sulphide can the killifish tolerate at the whole-animal level?
(ii) What physiological and biochemical changes occur during exposure to sulphide?
(iii) How much sulphide is inhibitory to killifish cytochrome *c* oxidase?
(iv) What accounts for the high sulphide tolerance of the killifish?
(v) Is anaerobic metabolism an important mechanism in sulphide tolerance?
(vi) Is sulphide tolerance constitutive? Is it improved by acclimation?

## II. MATERIALS AND METHODS

### EXPERIMENTAL ANIMALS

The California killifish used in the experiments consisted of juveniles and adults 50–150 mm in total length and 3–8 g in body weight. They were collected by minnow traps mostly from a creek in the Kendall-Frost salt marsh reserve in the northeast corner of Mission Bay in San Diego, California during winter and spring in 1988–1991.

### SULPHIDE EXPOSURE EXPERIMENTS

The killifish were exposed to sulphide in flow-through aquaria in which sulphide and fully aerated sea water from reservoirs flowed in continuously by peristaltic pumps. Seawater flow rate was 100 ml min$^{-1}$. Stock solutions of sulphide, prepared from thoroughly washed and dried crystals of $Na_2S.9H_2O$ dissolved in nitrogen-bubbled distilled water, was diluted 100-fold in the aquaria. Turnover time for water in the aquaria was 40 min, and oxygen concentrations at the outflows were 50–80% of saturation depending on treatment.

Control fish in the aquarium not receiving sulphide suffered no mortality. Water temperature during the tests was 14–18° C.

Long-term sulphide tolerance was determined by exposure of groups of 10 killifish to different concentrations up to 800 µM sulphide for 96 h. The 96-h $LC_{50}$, the lethal concentration for 50% of the fish was computed by probit analysis. Short-term tolerance was determined by exposure to different concentrations up to 8 mM sulphide for 8 h. In one experiment, 10 California killifish were exposed to each of the following sulphide treatments: 500 µM for 72 h, 1 mM for 8 h, 2 mM for 8 h, and 5 mM until death of 50% of the fish. In a subsequent experiment, duplicate aquaria were stocked with 12 killifish each and exposed to 200 µM, 1 mM, 2 mM, 5 mM and 8 mM sulphide for 8 h. At 2-h intervals, three fish were removed from one aquarium and analysed for haemoglobin spectra, haematocrit, haem concentration, and for sulphide and sulphide oxidation products in the blood (below).

A separate experiment was conducted to see whether killifish shifted to anaerobic metabolism during sulphide exposure. Fish that had been held in the laboratory for 6 months were stocked in the flow-through aquaria in four groups of 25 fish each: (i) fish exposed to 200 µM for 6 days; (ii) fish exposed to 700 µM sulphide for 3 days, and two control groups, one run side by side with each treatment. Fish from treatment and control aquaria were sampled 2 h into the exposure and every day for 6 days in 200 µM, and for 3 days (when all fish died) in 700 µM. During each sampling period, three control and three sulphide-exposed fish were removed, and assayed for blood lactate and enzyme activities in tissue homogenates (below).

Another experiment was made to determine the ' nature/acclimation ' basis of sulphide tolerance in the killifish. Sulphide tolerance may be due to a heritable genetic program (a constitutive basis), or to adjustments individuals make during their lifetimes (an acclimation effect), or to both. The approach taken to determine a constitutive basis was to remove killifish from the salt marsh, keep them in sulphide-free water in the laboratory for a period of months (' de-acclimation ', a term provisionally used for brevity's sake to mean ' acclimation to sulphide-free water in laboratory holding tanks '), and test them for *whole-animal* sulphide tolerance and for *mitochondrial* sulphide oxidation capacity. Conversely, killifish were acclimated in low sulphide (below the previously determined 96-h $LC_{50}$ but probably higher than typical field levels) and tested similarly. Thus, three groups of killifish were exposed to 5 mM sulphide for 8 h: (i) fish newly caught from the salt marsh; (ii) fish de-acclimated for 1·5 months in the laboratory; and (iii) fish acclimated in 200 µM sulphide for 7 days. The control group consisted of newly-caught fish also placed in the aquaria for 8 h but not exposed to 5 mM sulphide. The first two groups were tested with three replicate aquaria with 20 fish each, the third and the control groups with two replicates. After 6–8 h when most sulphide-exposed fish were dying, five dying fish were removed from each group, and blood and other tissues were fixed in monobromobimane and analysed by HPLC (below).

In this paper, ' sulphide ' refers to total dissolved sulphide (the sum of $H_2S$, $HS^-$ and $S^=$), unless otherwise specified. At environmental and physiological pH values, the $HS^-$ anion and the gaseous $H_2S$ forms are the important forms. Uncharged $H_2S$ freely diffuses across membranes, and sulphide toxicity to animals can best be approximated by the $H_2S$ concentration. Thus, the toxic sulphide concentrations will all be recalculated as $H_2S$ in the discussion.

## MEASUREMENT OF BLOOD PARAMETERS

Killifish from the 8-h tolerance tests at different sulphide concentrations were bled via the caudal vein into heparinized microcapillary tubes (length 75 mm, internal diameter 1·15 mm). The tubes were spun for 5 min in an IEC Model MB microhaematocrit centrifuge at 13 460 × *g*, and the haematocrit (packed RBC volume as percent of total blood volume) determined using a reader (microcapillary tubes, centrifuge and reader all from Fisher Scientific). The volume of the packed RBC was calculated to be $\pi r^2 h$ or 1·0387 *h*, where *h* is the height in the capillary tubes. The packed RBC were lysed in 0·2 or 1 ml distilled water and the clear supernatant was scanned for haemoglobin spectra and assayed for haem concentration. Formation of sulphhaemoglobin (SHb) and ferric haemoglobin

($Hb^+$), both indicators of impairment of oxygen transport, was monitored with a Perkin–Elmer Lambda 4A spectrophotometer with software from Softways (San Diego, California) using methods described earlier (Bagarinao & Vetter, 1992). Haem concentration was determined by adding known volumes of haemolysates to 2 ml Drabkin's reagent (Sigma assay kit ♯525), reading the absorbance of the ferric haemoglobin-cyanide derivative at 540 nm after 5 min, and calculating with the extinction coefficient 11 $\text{mM}^{-1}\,\text{cm}^{-1}$.

## CHROMATOGRAPHY OF SULPHUR COMPOUNDS

Sulphide is the most reduced form of sulphur and can be oxidized to elemental sulphur, thiosulphate, sulphite, and/or sulphate depending on the conditions and the organisms involved. The monobromobimane-HPLC method is able to fix and measure sulphide and other reduced sulphur compounds in the same samples (Fahey & Newton, 1987; Vetter *et al.*, 1987, 1989), and has been crucial to our studies of sulphide metabolism by whole animals, mitochondria and blood (Bagarinao & Vetter, 1989, 1990, 1992). During the 8-h tolerance experiments on the killifish, blood, heart/spleen (blood-rich tissues, combined because of small mass) and liver (not as blood-rich) were removed from sulphide-exposed individuals as well as controls and analysed by monobromobimane-HPLC. Various tissues from killifish in the ' nature/acclimation ' experiment were similarly analysed.

## ENZYME ASSAYS

The activities of two key enzymes, cytochrome *c* oxidase (EC 1.9.3.1; ferrocytochrome *c*: oxygen oxidoreductase) and lactate dehydrogenase (LDH; EC 1.1.1.27; $NAD^+$: L-lactate oxidoreductase) were determined spectrophotometrically at 20° C. Tissues of killifish were homogenized in 4 or 9 volumes of 10 mM Tris pH 7·2 and centrifuged for 5 min at 2000 × *g* at 5° C. Each tissue homogenate was assayed in three replicates. For cytochrome *c* oxidase, the 2-ml assay mixture contained 100 mM potassium phosphate pH 6·0, 0·5 mM EDTA and 50 µM reduced cytochrome *c*. Addition of 25 µl of the tissue supernatants initiated the reaction. Activities were calculated from the linear rate of decrease in absorbance at 550 nm within the first 1–2 min, using the extinction coefficient 18·5 $\text{mM}^{-1}\,\text{cm}^{-1}$. Sulphide concentrations inhibitory to cytochrome *c* oxidase in tissue homogenates (*in vitro*) were determined by adding microlitre amounts of sulphide to the assay mixture to achieve final concentrations up to 5 µM. The 50% inhibitory concentration, $IC_{50}$, was estimated by transforming activity data into percent inhibition, plotting them against the logarithm of sulphide concentration and fitting linear regression lines. In addition, inhibition of cytochrome *c* oxidase *in vivo* was monitored during the experiment on anaerobic metabolism.

During the latter experiment, LDH was also assayed in control fish and fish exposed to sulphide for different lengths of time. LDH activity was assayed in 2 ml buffer containing 80 mM imidazole pH 7·0, 200 µM NADH, 5 mM pyruvate and 10 µl tissue homogenate, by following the decrease in absorbance at 340 nm, and calculating with the extinction coefficient 6·22 $\text{mM}^{-1}\,\text{cm}^{-1}$.

## LACTATE ASSAY

Lactate accumulation was used as an indicator of the shift to, and the extent of, anaerobic metabolism in the California killifish during sulphide exposure. Whole blood was obtained by microcapillary tubes and promptly prepared for lactate determination. Samples were transferred into microcentrifuge tubes, diluted with three volumes of ice-cold 6% perchloric acid to precipitate the proteins, and stored frozen until assay at the end of the experiment. Lactate was assayed spectrophotometrically, using Sigma Diagnostics procedure ♯826-UV but scaled down to 750 µl assay volume. The assay mixture contained 197 mM glycine pH 9·2, 164 mM hydrazine, 12·3 units lactate dehydrogenase, 1·85 mM NAD, and 25 µl supernatant of the precipitated blood samples (4 × dilution). The mixture was incubated at 37° C for 30 min, and the absorbance at 340 nm was recorded. Lactate was estimated from the absorbance of NADH, using the extinction coefficient 6·22 $\text{mM}^{-1}\,\text{cm}^{-1}$, and allowing for the dilution of the blood sample. Each blood sample was assayed in three replicates.

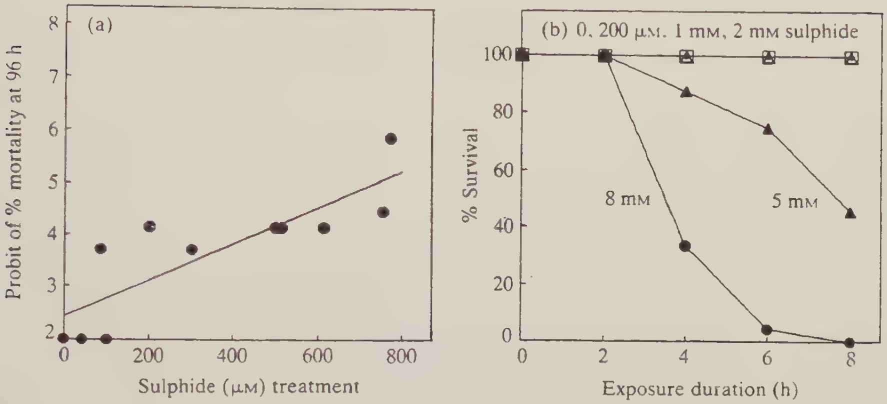

FIG. 1. Tolerance of California killifish to sulphide, determined in a flow-through oxygenated aquarium system. (a) 96-h tolerance; each point is per cent survival among 10 fish. The regression equation is $y=2{\cdot}4+0{\cdot}0037x$, $r^2=0{\cdot}72$, where $y$ is the probit value and $x$ is μM sulphide. (b) Tolerance of fish exposed to high sulphide concentrations for up to 8 h; each point is the average survival in two aquaria with 12 fish each.

## ASSAY OF SULPHIDE OXIDATION CAPACITY OF MITOCHONDRIA

Killifish mitochondria have previously been shown to rapidly oxidize low micromolar concentrations of sulphide exclusively to thiosulphate, a reaction that is stoichiometrically and obligately linked to oxygen consumption (Bagarinao & Vetter, 1990). Mitochondrial oxygen consumption in the presence of sulphide is therefore a direct measure of the sulphide oxidation capacity of killifish mitochondria. To determine whether mitochondrial sulphide oxidation was constitutive and/or improved by prior acclimation, mitochondria were isolated from five groups of killifish and assayed for oxygen consumption in the presence of sulphide. The five groups consisted of 40 fish each: (i) newly caught; (ii) de-acclimated for 1 month; (iii) de-acclimated for 2 months; (iv) acclimated to 200 μM sulphide for 10–12 days (with 20% mortality); and (v) acclimated to 500 μM sulphide for 10–12 days (with 50% mortality). Three mitochondrial preparations were made on three consecutive days from each group, each preparation from the livers of 10 killifish (seven fish for group 5). Each mitochondrial preparation was assayed three times in the presence of 3 mM succinate (a control substrate) and 10, 20, 50 and 75 μM sulphide according to methods described by Bagarinao & Vetter (1990).

## STATISTICAL ANALYSIS

Analysis of variance (ANOVA) and related tests were done by hand according to Zar (1984), and probit analysis with the BMDP computer program.

# III. RESULTS

## SULPHIDE TOLERANCE OF WHOLE FISH

Mortality after 96-h exposure to different concentrations of sulphide is shown in Fig. 1(a). The 96-h $LC_{50}$ calculated from probit transformation of the data was 700 ± 364 μM (95% confidence limits) total sulphide in oxygenated sea water at 14–18° C. In the short-term tolerance experiments, no killifish died in the controls and treatments up to 2 mM [Fig. 1(b)]. However, 50% of killifish exposed to 5 mM sulphide died in 3 h in one experiment, and in 6–8 h in the other. Half of the fish exposed to 8 mM sulphide died in 2–4 h. In the course of acute sulphide exposure, the fish at first huddled together with increased opercular and pectoral fin

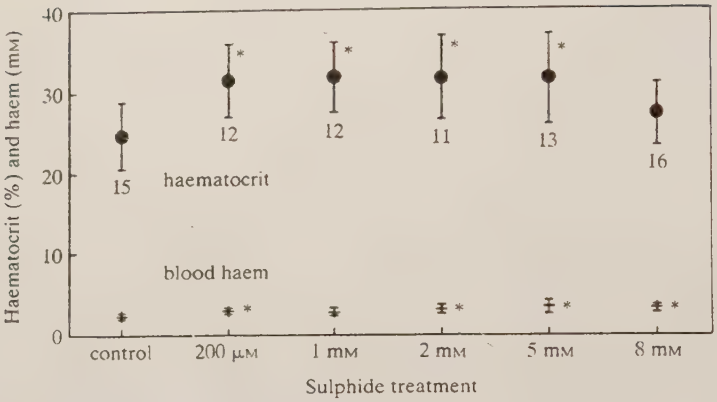

FIG. 2. Haematocrit and haem concentration (mean ± S.D.; sample sizes indicated on the haematocrit curve: same sample sizes for the haem curve) in fish from different sulphide treatments. Asterisks indicate significant differences from control values (ANOVA and two-tailed Dunnett's test. *q* values of $P<0.05$).

movement. This was followed by laboured ventilation, swimming to the surface and gulping air, and by frenzied attempts to leave the water. Poisoned fish lost equilibrium, swam awkwardly, ventilated long and deep, and finally turned over on their backs. Fish turned a darker colour during sulphide exposure.

Survival of killifish in 5 mM sulphide was improved by prior acclimation to 200 μM sulphide for 7 days. Newly-caught killifish suffered 75 ± 27% mortality (mean ± S.D., $n=3$ replicate aquaria, with a total of 64 fish); de-acclimated fish, 86 ± 5% ($n=3$, total 63 fish); and acclimated fish, only 23 ± 4% ($n=2$, total 40 fish). Mortality in the acclimated group was significantly different from the de-acclimated group, but neither was significantly different from the newly-caught group (one-way ANOVA and Tukey's test, *q* values of $P<0.05$).

## HAEMATOCRIT AND BLOOD HAEM CONCENTRATIONS

The haematocrit was 24·7 ± 4·1% and whole blood haem concentration was 2·4 ± 0·4 mM (mean ± S.D., $n=15$) in control killifish not exposed to sulphide. Significant increases in these parameters were observed in sulphide-exposed fish (Fig. 2). These increases occurred within the initial 2 h of sulphide exposure, and did not significantly change thereafter. Killifish dying in 8 mM sulphide did not show the haematocrit response.

## SHb OR $Hb^+$ FORMATION

Only two of 60 killifish (including 20 dead ones) examined after exposure to 200 μM to 8 mM sulphide showed some sulphhaemoglobin (SHb) in the bloodstream ($A_{618}/A_{576}$ ratio = 0·142–0·172). None of the fish examined showed any ferric haemoglobin ($Hb^+$) nor ferric haemoglobin sulphide ($Hb^+S$). Thus, death of killifish within 2–8 h in 5 mM and 8 mM sulphide was not due to significant SHb formation or impairment of oxygen transport.

Earlier experiments *in vitro* showed that killifish haemoglobin converted to SHb within minutes in 5 mM sulphide and within hours in 1 mM sulphide (Bagarinao &

Vetter, 1992). Thus, 1–5 mM sulphide is possibly the threshold concentration for impairment of oxygen transport in the killifish.

## SULPHIDE AND THIOSULPHATE IN TISSUES

In terms of the diffusible form of sulphide in sea water of pH 8·3, the concentrations used in the short-term tolerance experiments (200 μM to 8 mM) were equivalent to about 12–480 μM $H_2S$. If the blood equilibrated with the ambient sulphide and no oxidation occurred, it would have contained about this much sulphide. Figure 3 shows the sulphide and thiosulphate concentrations in the blood (a), spleen/heart (b) and liver (c) of fish from different sulphide treatments. Since the blood was used for other determinations (above), HPLC analysis of blood was done only for control fish, fish 6–8 h in the lethal 5 mM sulphide, and fish 11 days in non-lethal 200 μM sulphide from another experiment. Some sulphide (3 ± 1 μM, mean ± S.D., $n = 8$) was detected in blood from control fish, and this increased only two- to three-fold in fish from both the short-term 5 mM and the long-term 200 μM sulphide treatments. In contrast to the low sulphide concentrations, thiosulphate measured 71 ± 23 μM in controls, 303 ± 230 μM in the 200 μM treatment, and significantly higher at 853 ± 539 μM in the 5 mM treatment.

The heart/spleen and liver were analysed for more of the high-sulphide treatments [Fig. 3 (b, c)]. In these tissues, as in the blood, sulphide remained relatively low while thiosulphate increased much more with sulphide exposure. Fish in the lethal 5 mM and 8 mM sulphide treatments had, respectively, 30 ± 21 μM and 46 ± 24 μM sulphide in the heart/spleen, and 6 ± 9 μM and 35 ± 39 μM sulphide in the liver. Maximum thiosulphate concentrations noted were 956 μM in the heart/spleen and 680 μM in the liver in the 8 mM sulphide treatment.

Sulphide and thiosulphate concentrations in the blood and other tissues of fish from the ‘ nature/acclimation ’ experiment are shown in Table I. The brain had the highest sulphide concentration among the tissues examined. Such high sulphide level in the brain probably contributed to death of the fish. Blood sulphide concentrations were low and not significantly different among the three groups exposed to 5 mM sulphide nor between these and the controls. Thiosulphate concentrations were high and not significantly different among the three groups exposed to 5 mM sulphide; those from the newly-caught and acclimated groups were significantly elevated relative to the controls (one-way ANOVA and Tukey's test, $q$ values of $P < 0{\cdot}01$). Other tissues had lower thiosulphate levels than the blood. Statistical tests were not made for other tissues because of small sample sizes.

## INHIBITION OF CYTOCHROME *C* OXIDASE BY SULPHIDE

Figure 4(a) shows *in vitro* inhibition of cytochrome *c* oxidase of the killifish, as assayed in tissue homogenates. Inhibition of the enzyme was concentration-dependent over a range up to 5 μM sulphide. The $IC_{50}$ estimates ranged from 426–464 nM in the heart and brain, to 750 nM in muscle [Fig. 4(b)]. These inhibitory concentrations were very low, and showed that even a sulphide-tolerant fish had a sulphide-sensitive enzyme.

*In vivo* inhibition of cytochrome *c* oxidase was also observed during the experiment to determine shift to anaerobic metabolism. There was no mortality among the killifish during the 6-day 200 μM sulphide treatment, but 50% mortality during the 3-day 700 μM treatment. Cytochrome *c* oxidase was inhibited 50–90%

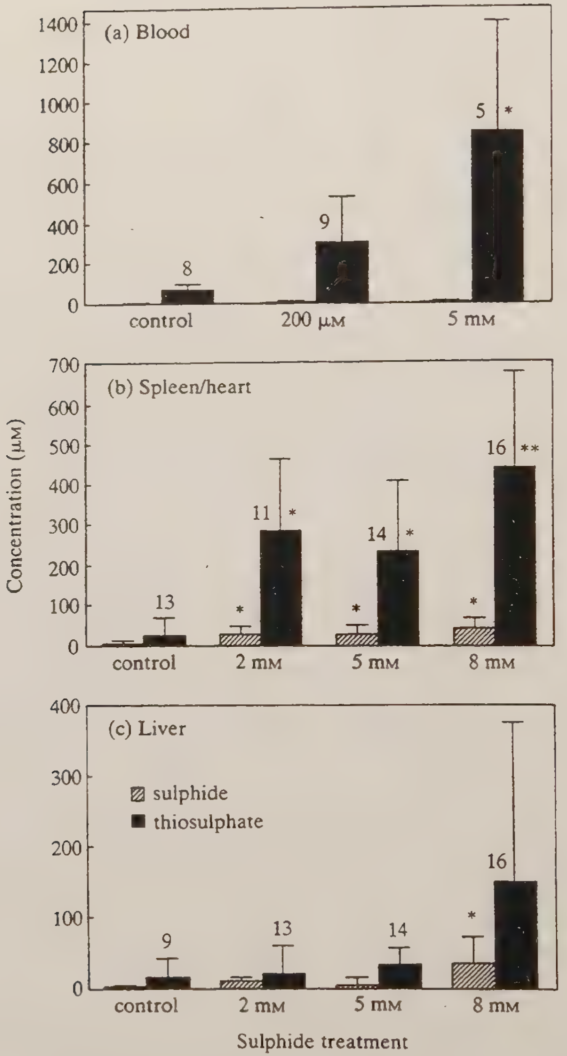

FIG. 3. Sulphide and thiosulphate concentrations in tissues of California killifish from the sulphide treatments (mean ± S.D.; sample sizes indicated on the bars). (a) Blood. Sulphide concentrations very low and not different between control and sulphide-exposed fish. Thiosulphate concentrations significantly elevated in fish from the 5 mM sulphide treatment. (b) Spleen/heart. Sulphide and thiosulphate concentrations significantly higher in fish from all treatments than in controls. (c) Liver. Sulphide concentration in fish from the 8 mM treatment significantly higher than in controls and the other sulphide treatments. No significant differences in thiosulphate concentration. Based on ANOVA and Tukey's test, *q* values of $P < 0.05$ (*) and $P < 0.01$ (**).

in the gill, 10–50% in the brain, and 0–50% in muscle (Table II). In fish that died in 700 μM sulphide, only the gill showed nearly complete inhibition (by 90%) to account for death. Liver activity did not seem inhibited and was even 50% stimulated in low sulphide. It must be noted that at least some reactivation of the inhibited enzyme may have taken place during preparation of homogenates and the 2–6 h between sampling and assay.

TABLE I. Sulphide and thiosulphate concentrations (mean ± S.D., $n$ = number of fish) in tissues of three groups of California killifish exposed to 5 mM sulphide for 6–8 h: newly-caught from the salt marsh, de-acclimated 1·5 months, and acclimated in 200 μM sulphide for 7 days. Some tissue samples were pooled (e.g. 5 in 1)

| Group | Tissue | *n* | Sulphide (μM) | Thiosulphate (μM) |
|---|---|---|---|---|
| Newly-caught, then 5 mM sulphide | | | | |
| | gill | 2 | 19 ± 1 | 61 ± 23 |
| | blood | 5 | 8 ± 7 | 853 ± 539 |

| | kidney | 3 | 1 ± 1 | 21 ± 2 |

## ANAEROBIC GLYCOLYSIS DURING SULPHIDE EXPOSURE

Control unexposed killifish had 3·6 ± 1·4 mM lactate (mean ± S.D., $n = 30$) in the blood. When killifish were exposed to 200 μM sulphide for 6 days, anaerobic glycolysis came into play and blood lactate increased three-fold to a maximum of 10·8 ± 6·5 mM ($n = 3$) (Fig. 5). When killifish were exposed to 700 μM sulphide for 3 days, blood lactate increased 10-fold to 37·3 ± 4·2 mM ($n = 3$) at 72, but the fish died. Metabolic acidosis probably compounded the inhibition of cytochrome oxidase and caused the death of killifish in the 700 μM treatment. The lower lactate levels at 144 h in 200 μM sulphide were measured 8 h after the sulphide supply ran out (Fig. 5), and showed that fish stopped producing lactate.

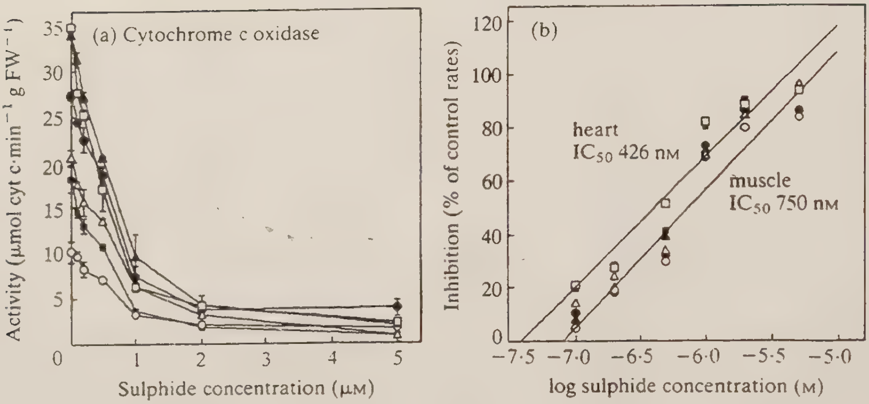

FIG. 4. Inhibition of cytochrome *c* oxidase in tissue homogenates of California killifish. (a) Enzyme activity against sulphide concentration [S], mean ± S.D. of three assays at each sulphide concentration using pooled homogenates from three fish. (b) Same data transformed as % inhibition against log [S] for estimation of the $IC_{50}$, the 50% inhibitory sulphide concentration. Only the two most extreme curves for the heart and the muscle are drawn. —●—, Gill; —■—, brain; —▲—, liver; —○—, muscle; —△—, kidney; —□—, heart.

Lactate dehydrogenase activity in killifish tissues assayed *in vitro* showed no significant change during sulphide exposure (Table II), and could not explain the increased lactate concentration in the blood. White muscle LDH had by far the highest activity, consistent with its primarily anaerobic function. In the sulphide exposure experiment, LDH activity was measured 5–8 h after removal of tissues from the fish (because cytochrome *c* oxidase was assayed first) and the delay probably affected the rates. When measured more promptly, killifish LDH activities were higher (muscle, 698 ± 149; liver, 170 ± 37; gill, 88 ± 20; brain, 141 ± 12; heart, 252 ± 13; blood, 13 ± 4 μmol pyruvate $min^{-1}$ g fresh $weight^{-1}$, $n = 4–5$).

### MITOCHONDRIAL OXIDATION OF SULPHIDE

Mitochondrial respiration was stimulated by 10–20 μM sulphide, with maximal rates around 15 nmol sulphide $min^{-1}$ mg $protein^{-1}$, and by 50 μM sulphide at half-maximal rates (Fig. 6), similar to earlier results (Bagarinao & Vetter, 1990). The toxic level for killifish mitochondria is therefore 50 μM sulphide. Mitochondrial sulphide oxidation capacity was significantly higher in fish acclimated in 500 μM sulphide for 10–12 days, compared with those acclimated in 200 μM, newly-caught, or de-acclimated for 1–2 months (Fig. 6). Killifish de-acclimated for 1–2 months showed rates the same as for newly-caught fish.

## IV. DISCUSSION

### MODEL OF SULPHIDE TOLERANCE

Consider the schematic in Fig. 7. Cytochrome *c* oxidase is located in the inner membrane of the mitochondria, within the cell, bathed by the blood, in the fish. Sulphide in the water has to diffuse across several barriers to reach the enzyme. Toxicity depends on the balance between the rate at which sulphide diffuses

TABLE II. Cytochrome *c* oxidase activity and lactate dehydrogenase activity in tissues of the California killifish during sulphide exposure. Values are mean ± S.D. ($n = 3$ fish, except control group $n = 6$). All fish were alive at sampling, except those in 700 μM sulphide at 72 h. Assays for cytochrome *c* oxidase were done 2–6 h after, and for LDH 5–8 h after removal of fish from aquaria

*Recovery 8 h after a 136-h sulphide exposure.

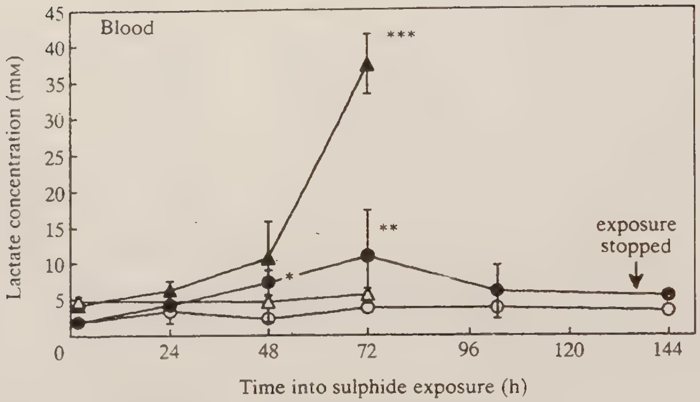

FIG. 5. Blood lactate concentrations in California killifish exposed to 200 and 700 μM sulphide. Control (unexposed) fish sampled at the same time and in the same manner as exposed fish to control for lactate production due to handling. Arrow indicates when the sulphide input stopped. Data for 144 h represent return to near-normal level. Asterisks indicate significant differences from respective controls and other time points, based on two-way ANOVA and Tukey's test, $q$ values of $P<0.05$ (*), $P<0.01$ (**), and $P<0.001$ (***). —▲—, 700 μM; —△—, control; —●—, 200 μM; —○—, control.

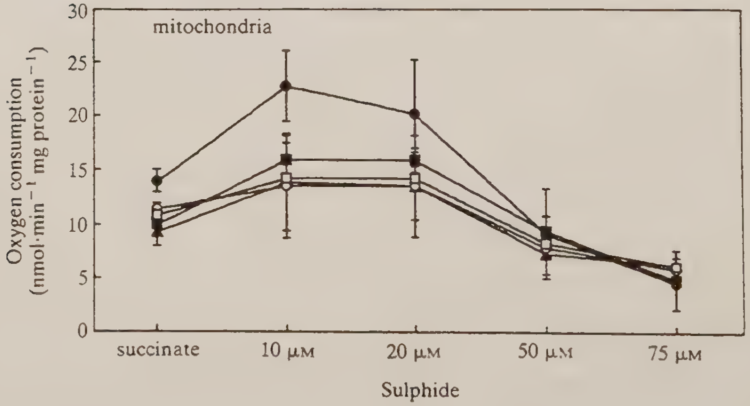

FIG. 6. Mitochondrial sulphide oxidation monitored as oxygen consumption rates (mean ± S.D., $n=3$ mitochondrial preparations, each from 7–10 fish) as a function of de-acclimation and acclimation. Mitochondria were removed from five groups of fish: (i) acclimated in 500 μM sulphide for 10–12 days; (ii) acclimated in 200 μM sulphide for 10–12 days; (iii) newly-caught from salt marsh; (iv) de-acclimated for 1 month; and (v) de-acclimated for 2 months. Mitochondrial sulphide respiration was significantly higher in the group acclimated in 500 μM sulphide for 10–12 days than in the other four groups (two-way ANOVA and Tukey's test, $q$ value of $P<0.05$). —●—, acclimated 500 μM; —■—, acclimated 200 μM; —▲—, newly-caught; —○—, de-acclimated 1 mo; —□—, de-acclimated 2 mo.

towards the enzyme (which depends on external sulphide concentration and pH) and the rate at which sulphide is detoxified by agents external to the enzyme. Any physiologically important sulphide detoxication system must be able to oxidize sulphide at a rate equal to the flux rate and must have sufficiently high affinity to

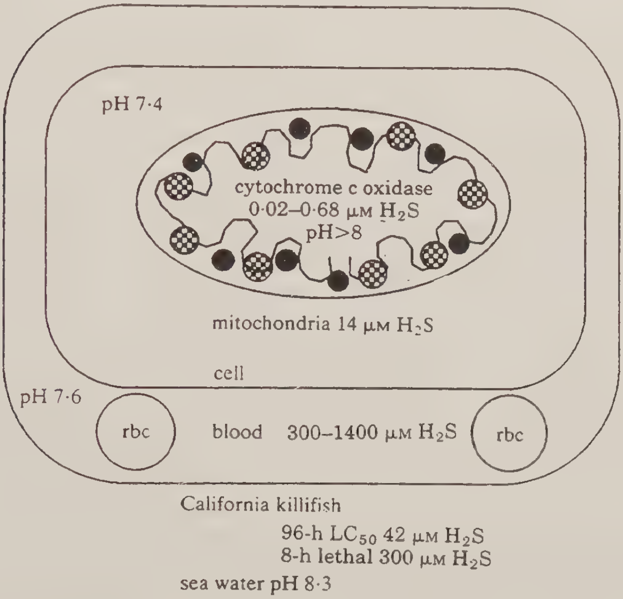

FIG. 7. Model of sulphide tolerance in the California killifish. Cytochrome *c* oxidase (larger circles) is located in the inner membrane of mitochondria. Cytochrome *c* (smaller circles) is located in the intermembrane space. The mitochondria are in cells, the cells are bathed by the blood, and the whole fish is exposed to sulphide in sea water. Sulphide has to diffuse across several barriers to reach the enzyme. Toxicity depends on the balance between the diffusion rate of sulphide towards the enzyme and the rate at which sulphide is detoxified by agents and mechanisms external to the enzyme. Drawn in the model are $H_2S$ concentrations recalculated from the total sulphide concentrations experimentally derived for the killifish in this and other papers (Bagarinao & Vetter, 1989, 1990, 1992).

rapidly reduce sulphide concentration to below that inhibitory to cytochrome *c* oxidase.

The cytochrome *c* oxidase of the killifish is inhibited by nanomolar sulphide. If assayed in homogenates, i.e. with the enzyme in a relatively ‘intact’ cellular environment, the 50% inhibitory concentration is 426–750 nM sulphide (Fig. 4). If assayed in tissue supernatants, i.e. with the enzyme detached from membranes and other cell components, the 50% inhibitory concentration is 24–184 nM sulphide (Bagarinao & Vetter, 1989). Isolated killifish mitochondria are 50% inhibited by 50 μM sulphide (Fig. 6; also Bagarinao & Vetter, 1990). Killifish blood is damaged (converted to SHb) at 1–5 mM sulphide *in vitro* (Bagarinao & Vetter, 1992). At the whole-animal level, 50% of the killifish tolerate 700 μM sulphide for 96 h, and 5 mM sulphide for 8 h (Fig. 1).

Toxic sulphide concentrations are better expressed as $H_2S$ since the latter is the diffusible form. $H_2S$ constituted 6% of total sulphide in sea water, pH 8·3, at which the whole-animal experiments were conducted, 28% at pH 7·4 at which mitochondria and haemoglobin were assayed, and 90% at pH 6·0 at which cytochrome *c* oxidase was assayed. Therefore, the whole-animal 96-h $LC_{50}$ for the California killifish is 42 μM $H_2S$ and the 8-h lethal concentration is 300 μM $H_2S$. The 50% inhibitory concentration for isolated mitochondria is 14 μM $H_2S$. The

50% inhibitory concentration for cytochrome *c* oxidase is 0·022–0·166 μM $H_2S$ in tissue supernatants and 0·383–0·684 μM $H_2S$ in tissue homogenates. The threshold concentrations for damage to haemoglobin is 280 μM $H_2S$ (over hours) or 1400 μM $H_2S$ (immediately). These values are plotted in the model in Fig. 7.

Two main conclusions may be derived from Fig. 7. First is that the mitochondria allow the killifish to withstand $H_2S$ concentrations two orders of magnitude greater than those that inhibit cytochrome *c* oxidase extracted from tissues. The sulphide concentration that inhibits mitochondria almost matches that which kills the fish. Thus, it appears that oxidative detoxication of sulphide by mitochondria is the chief mechanism behind the high sulphide tolerance of the killifish. If sulphide concentrations remain at relatively low concentrations in the water column, and they probably typically do in salt marshes, killifish mitochondria would be able to oxidize most of the sulphide before it reaches concentrations inhibitory to cytochrome *c* oxidase. Killifish mitochondria are capable of continuous detoxication of sulphide over several days (10–12 days in the 'nature-acclimation' experiment), and still do so upon subsequent isolation. Sulphide oxidation by killifish mitochondria is constitutive, and improved by acclimation (Fig. 6).

The sulphide-oxidizing mechanism in mitochondria probably consists of cytochrome *c* taking electrons from sulphide and passing them on to oxygen through cytochrome *c* oxidase. Based on the work of Moriarty & Nicholas (1969) and Nicholls & Kim (1981, 1982), we suggest that cytochrome *c* and cytochrome *c* oxidase are probably the 'sulphide oxidase', or components of the 'sulphide oxidase system' that some investigators have postulated (Powell & Somero, 1986; O'Brien & Vetter, 1990). The location of cytochrome *c* oxidase in the mitochondrial inner membrane, bathed in matrix fluid of $pH > 8$ fortuitously allows the enzyme to oxidize low concentrations of sulphide before being poisoned. The 0·02–0·68 μM $H_2S$ that is inhibitory to the enzyme is reached only when the matrix contains 0·33–11·33 μM total sulphide at pH 8·3. These high sulphide concentrations in the matrix in turn can only be reached when the concentrations outside the mitochondria are higher still.

Second is that killifish haemoglobin (blood) is relatively insensitive to sulphide and 'protects' cytochrome *c* oxidase by allowing the continued delivery of oxygen to mitochondria. The high threshold concentrations (280–1400 μM $H_2S$) required for SHb formation may explain why very few killifish exposed to high sulphide concentrations show any SHb in the blood. In killifish exposed to 5 mM sulphide in sea water pH 8·3, 300 μM $H_2S$ may be expected to occur in the blood by diffusion in the absence of sulphide uptake or detoxication. This concentration barely reaches the threshold for slow SHb formation and already equals the acute lethal concentration. Thus, the killifish die of sulphide poisoning not due to SHb formation.

Earlier studies have shown that killifish oxyhaemoglobin does not significantly oxidize sulphide, and that ferric haemoglobin, which does, occurs in negligible amounts (Bagarinao & Vetter, 1992). Other cellular factors may also be involved in the removal of free sulphide from solution, e.g. ferritin, disulphide-containing proteins, and S-methyltransferase (Baxter & van Reen, 1958; Cavallini *et al.*, 1970; Weisiger *et al.*, 1980). Their contribution is probably small because the reactions are non-specific. Although the killifish can shift to anaerobic metabolism during sulphide exposure (Fig. 5), glycolysis is of limited utility and eventually contributes to death.

## BIOCHEMICAL CHANGES DURING SULPHIDE EXPOSURE

Increases in the haematocrit and blood haem concentration in the killifish appear to be non-specific responses to stress induced by sulphide. Various studies suggest that haematological parameters may be useful indices of physiological response to environmental stress (Blaxhall, 1972). For example, teleosts respond to lowered dissolved oxygen or exercise by increasing the haem concentration (Cameron, 1970; Scott & Rogers, 1981). Such increases have been attributed to either water shifts from blood to tissue, or to compensatory haemoglobin production. Similarly, inhalation exposure of cats to 900 mg $l^{-1}$ $H_2S$ (=39 μM dissolved $H_2S$) for 5 min, and protracted exposure of rats to daily baths in 130–190 μM $H_2S$ for 20–30 min elevated the red blood cell counts and haemoglobin levels (in Beauchamp *et al.*, 1984). The significance of such haematological changes is not known. However, an increased blood haem concentration would enhance oxygen delivery to, and facilitate sulphide oxidation by mitochondria.

Occurrence of low sulphide and high thiosulphate concentrations in the tissues of fish exposed to 5 mM and 8 mM sulphide indicates that detoxication systems continue to work at these high concentrations, although for a limited time and at rates presumably lower than the sulphide influx rates. The highest thiosulphate concentrations are found in the blood, secondarily in blood-rich tissues such as the heart and spleen, and relatively low in the liver. Without evidence to the contrary, the blood may be assumed to oxidize sulphide. However, under nearly physiological conditions, the blood does not oxidize sulphide to thiosulphate at any appreciable rate, whereas liver mitochondria do so avidly (Bagarinao & Vetter, 1990, 1992). These results together with Fig. 3 and Table II suggest that thiosulphate produced in the liver (and probably other tissues) is readily transported into the blood. Accumulation of thiosulphate to high levels in the blood indicates that excretory mechanisms at best are slower than *in vivo* sulphide oxidation rates.

## ANAEROBIC METABOLISM

When California killifish are exposed to 200 μM sulphide (12 μM $H_2S$) for 6 days or to 700 μM sulphide (42 μM $H_2S$) for 3 days, cytochrome *c* oxidase is partially inhibited, anaerobic glycolysis comes into play, and blood lactate concentrations increase. The highest blood lactate concentrations (mean 37 mM) are observed in fish that had died in sulphide. These results are consistent with the high sulphide tolerance of the killifish, but also suggest that the upper limits of sulphide tolerance may be set by factors secondary to inhibition of cytochrome *c* oxidase, e.g. acidosis. When the channel catfish *Ictalurus punctatus* Rafinesque are exposed to 3 μM $H_2S$ for 30 min, cytochrome *c* oxidase in the brain and gills is inhibited 60–75%, and lactate concentrations in the blood increase more than three-fold (Torans & Clemens, 1982).

There is no evidence that the killifish has extraordinary anaerobic capacity. LDH activity per wet weight tissue does not increase during 3–6 days of sulphide exposure. The increase in blood lactate concentration during sulphide exposure is possibly due to a greater proportion of tissue mass shifting to anaerobic glycolysis with longer exposure. LDH activities in the killifish are not much different from those of other coastal fishes, after allowing for assay temperature, use of homogenates versus supernatants, intraspecific scaling with size, and differences in swimming and feeding habits (Sullivan & Somero, 1980; Castellini & Somero, 1981). In the congener *Fundulus heteroclitus* L., serum lactate concentration is 3·5 mM, and LDH activities are 227 units g wet weight$^{-1}$ in liver and 300 units g wet weight$^{-1}$ in skeletal muscle supernatants assayed at 25° C (Greaney *et al.*, 1980).

Lactate accumulation during anaerobic glycolysis leads to tissue acidosis (Pörtner *et al.*, 1984; Fievet *et al.*, 1987), a problem particularly for white muscle, which generates most of the lactate and has generally poor capillary circulation. Thus, there is need for adequate buffering capacity in muscle. Indeed, Castellini & Somero (1981) found similarly high buffering capacities in skeletal muscles of 11 species of actively foraging pelagic fishes and 10 species of diving mammals. The killifish probably has comparable muscle buffering capacity with these animals, and is able to continue anaerobic glycolysis for a period of days.

Shift to anaerobic metabolism during sulphide exposure may be a more important physiological strategy for sulphide tolerance among benthic invertebrates, which employ a greater variety of adaptive strategies and metabolic pathways (Shumway *et al.*, 1983; Oeschger & Storey, 1990; Levitt & Arp, 1991).

## CONSTITUTIVE BASIS OF SULPHIDE TOLERANCE AND EFFECT OF ACCLIMATION

The 'nature/acclimation' experiments on the California killifish have shown that survival in 5 mM sulphide, *in vivo* detoxication of sulphide to thiosulphate, and mitochondrial respiration on sulphide, are not different between newly-caught and de-acclimated fish, but are significantly improved by prior acclimation in 200 or 500 μM sulphide. In fact, killifish held in sulphide-free water for 6 months tolerate subsequent exposure to 700 μM sulphide for 3 days, and 200 μM sulphide for at least a week (in the separate experiment on anaerobic metabolism).

That de-acclimation or holding of killifish for months in the laboratory in sulphide-free water does not eliminate the ability of both whole fish and isolated mitochondria to oxidize sulphide is possibly because the sulphide-oxidizing enzyme system (cytochrome *c* and cytochrome *c* oxidase) is constitutive. The ability of mitochondria to oxidize sulphide has now been documented across four phyla (Bartholomew *et al.*, 1980; Lloyd *et al.*, 1981; Powell & Somero, 1986; Bagarinao & Vetter, 1990), likewise indicating a constitutive basis.

That acclimation improves fish survival in an otherwise lethal sulphide concentration, and enhances mitochondrial sulphide oxidation rates, is probably due to adjustments in the amounts or catalytic rates of cytochrome *c* and cytochrome *c* oxidase, or to a host of other factors that still have to be investigated. Acclimation is thus one more modifier of sulphide tolerance, which has been shown previously to vary with species, habitat, life stage or size, temperature, dissolved oxygen levels and pH (Theede *et al.*, 1969; Adelman & Smith, 1972; Smith & Oseid, 1974; Broderius *et al.*, 1977; Shumway *et al.*, 1983; Vetter *et al.*, 1987; Bagarinao & Vetter, 1989; Vismann, 1990; Levitt & Arp, 1991). Extensive research on other environmental factors (such as temperature, hypoxia and heavy metals) have shown that tolerance of animals to high levels is improved by prior exposure to lower levels. Cellular and molecular adjustments are made by the animal during the acclimation period (Shaklee *et al.*, 1977; Greaney *et al.*, 1980; Hobson & Birge, 1989), usually months, such that it can survive subsequently an otherwise lethal exposure. The longest sulphide acclimation period in this study was 12 days because it was a difficult experiment to do in the long term (large amounts of sulphide are needed in the flow-through exposure system and sulphide solutions have to be made up fresh every day).

In conclusion, the remarkably high tolerance of California killifish to sulphide can be explained chiefly by mitochondrial sulphide oxidation. Killifish exposed to sulphide shift to anaerobic metabolism, but fish with the most lactate die. Killifish blood does not catalyse sulphide oxidation significantly, or binds sulphide at environmental (low) sulphide concentrations. Sulphide tolerance and mitochondrial sulphide oxidation in the killifish have a constitutive basis and are improved by prior acclimation.

## ABSTRACT

Immunological detection of yolk protein was used to assess predation by pelagic amphipods (gammarid and hyperiid), mysids, and euphausiids on eggs and yolk-sac larvae of walleye pollock *Theragra chalcogramma* during 1988 and 1989. Consumption estimates were made on the basis of frequency of positive immunoassays, assay detection times (gut clearance time), predator abundance, and spatial overlap of predators and prey. From our results gammarid amphipods and euphausiids were important predators on eggs and yolk-sac larvae, respectively. Gammarid amphipods alone consumed about 14% of the standing stock of pollock eggs in 1989. These results were compared with those from clearance rate experiments of predators feeding on pollock eggs in 300-l bags. In general, clearance rate estimates of egg consumption were lower than those determined from gut contents.

**Key words:** walleye pollock, *Theragra chalcogramma*, predation, fish eggs, immunoassay

## INTRODUCTION

Predation is believed to be one of the major sources of mortality for marine fish eggs and larvae (Hunter, 1984; Bailey and Houde, 1989, and references therein). However, predation in the field, including identification of the major predators and how many prey they are eating, is poorly understood owing to difficulties of assessment.

Several methods are used to study invertebrate predation upon early stages of marine fishes, each with advantages and drawbacks. Laboratory-derived clearance rates of predators feeding on fish eggs and larvae have been applied to field estimates of predator abundances (Bailey and Yen, 1983; Monteleone and Duguay, 1988). This method has numerous problems; for instance, small-scale spatial overlap of prey and predators is not easily replicated in the laboratory, and it is difficult to extrapolate results under laboratory conditions to those in the sea. Predation also can be estimated from the difference between total and nutrition-related mortality (Hewitt et al., 1985; Leak and Houde, 1987); drawbacks to this method are that predators remain unidentified and both empirical estimates may be relatively imprecise, resulting in a low degree of confidence in predation estimates.

Gut contents of potential predators can be examined either visually or serologically. Difficulties with these methods include variable digestion rates, gut voiding, and feeding during net capture. Visual examination of guts has been particularly useful for studying fish predation on eggs (Hunter and Kimbrell, 1980; Brodeur et al., 1991), but larvae are believed to be digested very rapidly. This method has also been useful for estimating predation of gelatinous zooplankton on eggs and larvae (Moller, 1984; Purcell, 1989; Purcell and Grover, 1990). Serological techniques are most useful for marine crustacean predators that macerate their prey, which renders direct visual identification impossible (Feller et al., 1979). Theilacker et al. (1986) and Theilacker (1988) have used serological methods to study predation by euphausiids on northern anchovy *Engraulis mordax* eggs and yolk-sac larvae.

We studied invertebrate predation on walleye pollock (*Theragra chalcogramma*) eggs and yolk-sac larvae from Shelikof Strait, the major spawing area in the western Gulf of Alaska (Kendall and Picquelle, 1990). Peak spawning occurs during a two-week period in early April. Eggs are located near the bottom (150–250 m) in a concentrated patch (Kendall and Kim,

1989) and hatch after about 14 days at a water temperature of 5–6°C. Yolk-sac larvae (3–4 mm) move toward the surface and are generally distributed in the upper 150 m; they are still quite concentrated and located downstream from the eggs (Incze et al., 1989).

Mortality of walleye pollock eggs and early-stage larvae is high and variable. Daily egg mortality has been estimated at 10–30% (Kim and Gunderson, 1989). Estimates of daily larval mortality range from 6% to 15% (Incze et al., 1989; Yoklavich and Bailey, 1990). It has been proposed, although the evidence is scarce, that predation is the major source of walleye pollock egg (Kim and Gunderson, 1989) and larval mortality (Walline, 1983).

The objectives of the present study were (1) to identify invertebrate predators of walleye pollock eggs and yolk-sac larvae using serological techniques, (2) to estimate predation rates in the field, and (3) to compare predation rates in the field to those determined from clearance rates in 300-l bags.

## MATERIALS AND METHODS

### *Field methods*

The area of the main walleye pollock spawning aggregation in Shelikof Strait was initially sampled in a 18.5 × 18.5 km grid to define the distribution of pollock eggs and larvae during ichthyoplankton surveys in 1988 and 1989. Following these initial presurveys, plankton collections were made in areas of high egg and yolk-sac larval densities. Cruises were conducted aboard the NOAA ship *Miller Freeman*. Cruises from April 1 to 13, 1988 and from April 5 to 16, 1989, were termed "egg cruises," since eggs were predominant in catches. A cruise from 16 April to 2 May 1988 was termed the "yolk-sac cruise" even though eggs were also present, since hatching was occurring and sampling was directed to capture predators feeding on yolked larvae.

A 1-$m^2$ mechanically operated Tucker trawl with 505-$\mu$m mesh nets was deployed to sample predators at specific depth strata where the highest concentrations of eggs and yolk-sac larvae were expected to occur (Kendall and Kim, 1989; A. Kendall, NMFS, Seattle, personal communication). For egg predators the net was towed obliquely from 250 to 150 m. For yolk-sac larvae the net was towed obliquely from 150 m to the surface. Depth of sampling was monitored with an electronic bathykymograph. Volume of water sampled was estimated with a flowmeter in each net. To examine diel differences in predation, we tried to distribute the sampling effort equally between day and night.

Larger predators also were sampled during the yolk-sac cruise in 1988 using a 5-$m^2$ Methot frame trawl (Methot, 1986) equipped with a 2 × 3 mm oval mesh net. Oblique tows were made from 150 m to the surface.

Feeding on eggs and larvae in the codend of the nets (Hirota, 1984; Nicol, 1984) is a potential problem in sampling. A 1.5-mm mesh codend was used on all nets to allow pollock eggs and larvae to pass through the codend while predators were retained.

The contents of the codend were emptied into a sorting tray containing a slurry of iced seawater, and most of the large crustacean predators were removed quickly (<10 minutes), placed in microcentrifuge tubes, and stored at −80°C. The remaining sample was preserved in 5% buffered formalin in seawater. All specimens ≥5 mm (maximum dimension) in the crustacean groups Euphausiacea, Mysidacea, and Amphipoda (Hyperiidea and Gammaridea) were later identified to species and enumerated. Abundance was standardized to number per 10 $m^2$.

Because many predators make extensive vertical migrations extending outside the depth of our sampling, we adjusted predator abundance on the basis of the percentage of the total predator abundance that overlapped with egg or larval vertical distributions during the diel period. We approximated the vertical distribution of the dominant species in the four invertebrate groups and walleye pollock eggs and 3–4 mm larvae, presumed to be yolk-sac stage, using abundance data from four (two day and two night) MOCNESS tows (Wiebe et al., 1976), which were collected over eight depth strata from the surface to 250 m on April 21 and 24, 1988. Mesh size was 153 $\mu$m.

### *Laboratory methods*

For immunoassays, individual frozen specimens were placed on a microscope slide and allowed to thaw briefly. Digestive tracts were dissected from each specimen and placed into Protein Extraction Buffer (PEB; 10 mM Tris-HCl, 1 mM EDTA, pH 7.4). Gut fullness was visually estimated and recorded. Guts were transferred into 20 $\mu$l of chilled PEB and homogenized with a Duall disposable tissue grinder (1.5-ml volume; Kontes of California, Hayward, CA). Ten microliters of homogenate were spotted onto 0.45-$\mu$m nitrocellulose paper in a microfiltration apparatus and allowed to drain. The blots were kept at 4°C until the membrane appeared to be dry, usually 12–18 hours.

The nitrocellulose membrane was removed from the filtration apparatus and blocked in Blotto-wash (5% nonfat dried milk, 0.05% Tween-20, 0.01% antifoam A, phosphate buffered saline, pH 7.4; modifed from

Theilacker et al., 1986) for up to 24 hours. The remaining protocol for washes and rinses is described by Theilacker et al. (1986) with the following modifications. Ten percent normal goat serum was used in both the conjugate antibody preblock and the conjugate antibody incubation. Because nonspecific binding of euphausiid gut contents appeared to occur with the secondary antibody, two blots were run simultaneously; one was incubated with both the primary and the secondary antibody, and the second was incubated with the secondary antibody only. The primary antibody was a polyclonal rabbit-anti-pollock egg-yolk protein IGG fraction produced in New Zealand rabbits (Merati et al., unpublished manuscript). The primary antibody used in the immunoblots was diluted 1 : 5000 in Blottowash. The secondary antibody was a 1 : 3000 dilution of goat-anti-rabbit alkaline phosphatase (Biorad Laboratories, Richmond, CA). Invertebrate specimens whose guts were allowed to clear for 24 hours and walleye pollock eggs and yolk-sac larvae were used as negative and positive controls, respectively. The reaction was visualized by color development with NBT (*p*-nitro-blue tetrazolium chloride) and BCIP (5-bromo-4-chloro-3 indyl phosphate *p*-toluidine salt).

### *Consumption estimates*

The number of walleye pollock eggs or yolk-sac larvae consumed per 10 m$^2$ per day (C) by each predator species ($j$) was calculated by

$$C_j = \frac{A_j \cdot P_j \cdot N_j \cdot V_j}{D_j},$$

where

$A$ = predator abundance per 10 m$^2$,

$P$ = proportion of invertebrate guts testing positive for antigen,

$N$ = number of eggs or yolk-sac larvae per gut (assumed = 1),

$V$ = correction factor for incomplete vertical overlap (as described above),

$D$ = detection time of yolk protein in guts (d).

Detection time ($D$) of yolk protein was estimated by observing predators placed in jars with walleye pollock yolk-sac larvae. Predators that fed successfully were placed in jars containing either filtered seawater or algae at 6°C (average water temperature in the field) and were sacrificed at hourly intervals. These predators were frozen in liquid nitrogen and assayed for egg proteins.

The vertical overlap correction factor ($V$) was estimated from the percentage of predators found at each depth stratum ($i$) during the day ($P_{di}$) and night ($P_{ni}$), adjusted to the same depth stratum ($A_i$) where eggs and larvae are found by the following formula:

$$V = \frac{H_d \sum_{i=1}^{8} \min(P_{di}, A_i) + H_n \sum_{i=1}^{8} \min(P_{ni}, A_i)}{24},$$

where $H_d$ and $H_n$ are the hours of daylight and darkness during the sampling period.

Total consumption ($C_t$) for each life history stage of walleye pollock was estimated by summing over the four predator groups ($j$):

$$C_t = \sum_{j=1}^{4} C_j \cdot S,$$

where $S$ is stage duration (assumed to be 14 days for eggs and 7 days for yolk-sac larvae; Bailey and Stehr, 1986). The proportion of the total egg population consumed was estimated by dividing the number of eggs consumed by the number estimated to be available in the plankton at the nearest stations from the grid survey. This was not possible for yolk-sac larvae because of potentially high rates of extrusion through the 505-$\mu$m mesh nets (Lo, 1983).

### *Mesocosm study*

Clearance rate experiments of predators feeding on walleye pollock eggs were conducted at sea during the 1988 and 1989 egg cruises. Polyethylene bags (300 l) were filled with filtered seawater, immersed in a large water bath at ambient temperature (3–4°C), and covered with a black tarp to simulate light at depth. Most (36) experiments were conducted in daytime for 9–12 hours, although a few (4) experiments were conducted for 20–24 hours. Four predator types (gammarids, hyperiids, euphausiids, and mysids) were removed live from Tucker trawls and held in seawater at 4–6°C. Eggs were extruded from trawl-caught adults, fertilized, and reared at 4–6°C. Eggs were counted into each bag, and 5–6 predators of one type were added. Initial egg densities were 0.01, 0.1, and 1 l$^{-1}$ (low, medium, and high densities). Maximum egg densities estimated from oblique bongo tows in the Shelikof spawning area are from 0.2 to 0.6 l$^{-1}$, and actual densities over a narrower depth range would be considerably higher. From two to five replicate experiments were conducted for each density and predator type. Additional bags (one at low, two at medium, and three at high egg densities) without predators were used as controls for counting errors. Eggs were essentially neutrally buoyant. After each experiment, water from each bag was siphoned through a 333-$\mu$m mesh filter, the empty bag was rinsed three times, and the rinse water was likewise filtered. Clearance rates ($l \cdot \text{predator}^{-1} \cdot \text{day}^{-1}$) were calculated as

$$C = \{(\ln(n_i) - \ln(n_f)) \cdot V\} \cdot (NT)^{-1},$$

where $n_i$ is the initial egg density (number $\cdot$ $l^{-1}$), $n_f$ is the final egg density (number $\cdot$ $l^{-1}$), $V$ is the volume, $N$ is the predator number, and $T$ is the duration of the experiment in days (from Marin et al., 1986).

## RESULTS

Seventeen likely zooplankton predator species were caught in Tucker trawls; mean densities ranged from 0.15 to 864.18 $m^2$ (Table 1). Except for euphausiids, the major categories were dominated by one species. Specimens frozen for gut analyses were not identified by species prior to immunoassays in 1988. However, on the basis of the sorted portion of catches, we assume that almost all gammarids were *Cyphocaris challengeri*; most hyperiids were *Themisto pacifica*; most mysids were *Meterythrops robusta*; and all euphausiids were *Euphausia pacifica, Thysanoessa spinifera*, and *T. inermis* in 1988.

Because there was little difference in vertical distribution among predator species within each major grouping, we have combined these distributions (Fig. 1). Walleye pollock eggs mainly (>80%) were distributed below 150 m. Most (>75%) small, presumably yolk-sac, pollock larvae (3–4 mm S.L.) were located above 150 m. There were marked diel changes in vertical distributions of all predators except mysids, which were caught near-bottom in both night and day tows. Gammarids were mostly near-bottom in daytime and more evenly distributed in midwater at night. Most euphausiids were caught above 150 m in day and night tows, with a shift toward the surface at night. Hyperiids were distributed nearly uniformly through the water column, especially at night.

From the egg cruises of both 1988 and 1989, 11–16% of gammarid and hyperiid amphipods tested positive for walleye pollock egg yolk proteins (Tables 2 and 3). Mysids in 1988 and 1989 and euphausiids in 1988

[1] Insufficient number analyzed for 1989, taken from 1988 analysis.

tested 3–5% positive. From the yolk-sac cruise in 1988, 15.5% of euphausiids tested positive for yolk proteins, and only 1.7% of gammarids had positive reactions (Table 4). We found no evidence of day/night differences in the incidence of pollock egg yolk proteins in guts of any of the four predator groups (chi-square test: all $P > 0.05$).

Detection time of yolk protein in euphausiid guts varied between 1 and 4 hours, and all detection of antigen ceased after 3–4 hours for hyperiid and gammarid amphipods. There was no discernable difference in digestion time between predators placed in filtered seawater and predators placed in seawater with algae. We have therefore made the simplifying, and conservative, assumption that detection time was equal to 4 hours for all predators (including mysids, which were not available to be tested).

In 1988, gammarid and hyperiid amphipods were the most significant consumers of pollock eggs (5.39 and 4.18%, respectively). In 1989, all predators except hyperiids were much more abundant, and these higher abundances, along with higher incidences of predation, resulted in an increase in the number of eggs consumed by all predator groups from 11.06% (0.8% day$^{-1}$) in 1988 to 17.44% (1.2% day$^{-1}$) in 1989 (Tables 2 and 3). Gammarid amphipods were again the most important consumers of eggs.

From the yolk-sac cruise in 1988, euphausiids were the most important consumers of yolk-sac larvae (Table 4), contrasting with the findings of the major predators on eggs in 1988 (Table 2).

From bag experiments, clearance rates of the four predator types tested were greater at highest egg densities (i.e., at the three densities tested, the rates were not constant as expected) (Fig. 2). We suggest that this may have been because of the very low probability of a successful encounter at the lowest egg densities over the duration of the experiment. For example, at the highest egg densities the mean euphausiid clearance rate was only 0.3 l$^{-1}$ hour$^{-1}$ individual$^{-1}$; therefore during a 12-hour experiment the probability of five euphausiids capturing an egg at the low density of 0.01 eggs l$^{-1}$ is only about 16.6% (18 l cleared out of 300 l, with a probability of 0.01 that any one liter contains an egg: $1 - (99/100)^{18} = .1655$).

The number of eggs consumed in the sea, deter-

mined from mean and maximum clearance rates and observed densities of eggs and predators for 1988 and 1989, was compared with those from gut assays (Table 5). The number of eggs consumed from clearance rate experiments is 3–10 times lower than estimates derived from gut assays, except for euphausiids, which tend to have higher estimates based on clearance rates.

Immunoassays were conducted on guts of predators from the bag experiments. From 12 experiments in which no eggs were missing from the bags, 72 animals that presumably had eaten no eggs tested negative in immunoassays. From seven experiments in which eggs were consumed from the bags, four animals out of 42 tested positive.

## DISCUSSION

Invertebrate predators are an important source of mortality for fish eggs and larvae (Hunter, 1981; Bailey and Houde, 1989), but estimates of their impact have been made only recently (Theilacker et al., 1986; Theilacker, 1988; Purcell, 1985, 1989; Purcell and Grover, 1990). In this study, we surveyed a range of abundant crustacean predators using an immunological assay and made initial estimates of predation potential in order to focus future efforts. Our results indicate that gammarid and hyperiid amphipods are important predators on walleye pollock eggs and that euphausiids are significant predators on yolk-sac larvae of this species.

Biological and physical factors can influence predation rates (Purcell, 1985; Bailey and Houde, 1989); among these factors is the spatial and temporal overlap in distribution of predators and prey (e.g., Frank and Leggett, 1982). We found that the vertical overlap of walleye pollock eggs and larvae with crustacean invertebrate predators had a major effect on estimates of predatory impact. Euphausiids, which occur mostly in the upper 150 m, overlapped minimally with eggs but overlapped substantially with yolk-sac larvae; euphausiids were the major predator group on yolk-sac larvae but ate relatively few eggs. Gammarid and hyperid amphipods, on the other hand, are most concentrated at middle or lower depths, overlap to a greater extent with the developing eggs, and apparently consume them at relatively high rates.

There are many factors that can influence estimates of predation from both laboratory experiments and field assay of gut contents. Predation rates from analysis of predator gut contents were generally much higher than estimates from laboratory-derived clearance rates.

**Table 5.** Comparison of total egg consumption estimated from clearance rate experiments and gut content immunoassays in 1988 and 1989 per 10 m$^2$ over the 14-day egg residence time. Range of egg consumption estimates are based on mean and maximum clearance rates for each predator taxon. Mean egg abundance used to calculate consumption from clearance rates was 11,000 per 10 m$^2$ in 1988 and 48,000 per 10 m$^2$ in 1989. Predator abundances and corrections for vertical overlap are the same as in Tables 2 and 3.

| | | | 1988 | | 1989 | |
|---|---|---|---|---|---|---|
| Taxa | Mean clearance rate (l/day) | Maximum clearance rate (l/day) | Estimated no. eaten | Estimated from guts | Estimated no. eaten | Estimated from guts |
| Gammaridea | 0.8 | 2.0 | 6–15 | 602 | 282–675 | 6877 |
| Hyperiidea | 7.1 | 15.1 | 53–114 | 467 | 240–512 | 635 |
| Mysidacea | 0.6 | 1.8 | 3–10 | 110 | 78–233 | 872 |
| Euphausiacea | 7.1 | 18.9 | 26–70 | 57 | 192–515 | 95 |

There are several plausible reasons. First, capturing animals at depth with nets and bringing them to the surface could influence their physical condition and behavior, thus limiting their capabilities. Second, both *Cyphocaris* and *Themisto* tend to get trapped at the water–air interface in laboratory containers, effectively halting their feeding activity on suspended eggs. We did not notice this for individuals in the bags, but it remains a possible factor. Third, although the eggs appeared to be neutrally buoyant and well distributed in rearing jars, they may have been segregated from the predators in the bags, with predators accumulated at the sides, bottom, or top of the bags. This was probably a significant problem with mysids, which tend to remain near or on the bottom. From previous experiments conducted in 1-l jars, these same predators either did not eat fish eggs or ate them at low rates (Theilacker and Lasker, 1974; Bailey and Yen, 1983; Bailey and Stehr, 1986); however, they readily ate yolk-sac fish larvae. Confinement in small jars may also affect predator behavior, decreasing their ability to detect or handle fish eggs. De Lafontaine and Leggett (1987) found that for gelatinous predators, decreasing container size increased predation rates. Experiments by Monteleone and Duguay (1988) had different results; they found that clearance rates of the ctenophore *Mnemiopsis leiydi* decreased with decreasing container size. Predator species have different mechanisms for detecting and capturing prey; therefore their responses to container sizes are expected to vary.

Conversely, the immunoassays could have overestimated predation rates if there was codend feeding, if there were false positives, or if digestion rate estimates were too high. We used a codend with a mesh size that is considerably larger than the diameter of walleye pollock eggs, which should have minimized the capture of eggs and any codend feeding. Crustaceans used in bag experiments that did not consume eggs did not have any false positive reactions in the immunoassays. In addition, based upon animals that did consume eggs in bag experiments, the assays appeared to be relatively conservative. Our antibody-antigen reactions of predator gut contents was considerably weaker and more difficult to interpret than results of dilute yolk protein–antibody reactions. Antigenicity of the yolk protein was probably diminished during the digestion process. We suggest that in future studies, developing antibodies against partly digested (with trypsin or other enzyme) antigen be compared with antibodies against whole antigen. In addition, the reaction of predator guts with goat-anti-rabbit secondary antibody was a problem that we attempted to control by checking this reaction alone for each gut assayed. In retrospect, a nonreacting secondary antibody should be sought for future studies.

It was interesting that clearance rates estimated at low egg densities, similar to *in situ* values (0.01–0.1 eggs $l^{-1}$), were not constant, but rather increased with prey density. This observation could result from predators with low feeding rates combined with the short (10–24 hour) duration of experiments because the probability of ingesting prey is low. Experiments done with gelatinous zooplankton predators that feed upon fish eggs and larvae at higher rates and in which duration of experiments was longer (24–48 hours) have demonstrated constant clearance rates (Monteleone and Duguay, 1988; De Lafontaine and Leggett, 1987; Fancett and Jenkins, 1988); on the other hand, these are predators with linear or Type-I (Holling, 1959) functional responses. Animals that have a sigmoidal functional response, such as predators whose feeding activity decreases at low prey density, would be expected to have low clearance rates at low prey density.

Gut detection times of egg proteins were variable and not obviously influenced by alternative prey or continuous feeding. Immunoassay detection is based on the presence of antibody binding sites on the egg proteins. Digestion may influence the nature of these binding sites, and thus antigen digestion rates could be fast in relation to an assay based on total protein content. Thus our estimates of 4 hours for gut residence times is likely to be conservative. However, even halving detection times, thus doubling predation mortality, would not substantially alter our conclusions. Our antibody does not cross-react with algae or invertebrate eggs but does cross-react with yolk proteins from other fish species; in our field studies, cross-reactions with other fish eggs is an insignificant problem, since walleye pollock eggs comprised over 99% of all eggs caught in April cruises of 1988 and 1989 (Alaska Fisheries Science Center ichthyoplankton files, unpublished data).

Gut content assays may be conservative for several other reasons. First, predators may be defecating during the capture process. However, because the assay can detect nanogram amounts of egg protein, even a trace presence of yolk in the gut would be detected. Paradoxically, few predators from net catches were observed to have melanin in their guts compared with animals feeding in the laboratory. Although eggs have little melanin content until the eyes develop just before hatching, the absence of melanin may indicate that defecation occurred during the capture process. Second, animals testing positive in the assays were assumed to have eaten only one prey during the digestion interval; this provides the most conservative estimate and is supported by the low rate of feeding in the bag experiments. Finally, it is difficult to estimate the abundance of evasive predators such as euphausiids; problems with abundance estimates would apply equally to estimates of egg consumption from gut content and clearance rate methods.

Our estimates of daily egg mortality due to predation by pelagic crustaceans (0.8–1.2% $day^{-1}$) are low in relation to estimates of total egg mortality for walleye pollock (10–30% $day^{-1}$ from Kim and Gunderson, 1989). The immunoassay results, as discussed above, may be conservative, but other sources of mortality could also be significant. For example, pelagic fishes may consume large numbers of eggs, or nonpredatory mortality (e.g., developmental abnormalities) could be substantial. Predation rates from gut assays were still considerably higher than those estimated from bag experiments, indicating that bag studies may underestimate the impact of predators. Because both the bag and immunoassay results depend on good estimates of predator abundance, we recommend improvements in this area. Our results also demonstrated the importance of vertical overlap of predators and prey, and this should be included as a component of future predation studies.

## ACKNOWLEDGMENTS

We thank Drs. Arthur Kendall, Anne Hollowed, Gary Stauffer, and Gail Theilacker for their helpful reviews of this manuscript and Michael Helser, Akihiko Hara, Walt Dickoff, and numerous Fisheries Oceanography Coordinated Investigations (FOCI) staff for their assistance during this project. We again thank Dr. Kendall for use of MOCNESS data on eggs and larvae and Dr. Peter Ortner for access to MOCNESS samples for zooplankton vertical distribution. This is FOCI contribution No. 0160.

# APPENDIX A
# ANNOTATED LIST OF SHARK ATTACKS IN THE HAWAIIAN ISLANDS, 1779-1993, BY GEORGE H. BALAZS

The following list provides a case-by-case factual synopsis of the 104 known shark attacks in the Hawaiian Islands, from the earliest recorded event in 1779 to the most recent one in June 1993. Available information is also summarized here in separate tables covering the activity of the victim, the month of the attack and the species of shark involved.

Prior to the publication of my first assembled shark attack list in 1981 (co-authored with Alan K.H. Kam), no consolidated historical information of this nature was available for Hawaii. Old cases of shark attack were located through comprehensive searches of books, newspaper files and other sources. This is an ongoing process. I am grateful to Gail Bartholomew, Leighton Taylor, John Naughton and others for their continuing assistance in uncovering valid cases from Hawaii's past that warrant addition to the list.

Since 1981 nearly all new cases have been readily identified at the time of their occurrence when they appeared in Hawaii's newspapers and television reports. In many instances I have been able to personally interview the victim, or the last person to see the victim alive, in order to record first-hand accurate information to the extent that it is known. Autopsy and police reports have also been used to contribute meaningful data. A list of the literature and other sources used to document each case, too long to include here, has been deposited in the Pacific Collection of Hamilton Library, University of Hawaii at Manoa.

Forty-four (42.3 percent) of the 104 cases on the following list are tabulated as having involved a fatality. However, nine (20.5 percent) of these forty-four fatalities are considered to have been "likely" due to drowning or other causes, which was then followed by shark bite, dismemberment, and/or consumption. No cases have been included on this list in which a person was known with certainty to have been dead prior to being bitten by a shark. Cases involving fatality present special challenges to a compiler when there is no first-hand witness to the death, and medical evidence is inconclusive or nonexistent. In each such case I have used the best available information to render a professional judgment in assigning one of four footnoted categories to the fatality. It is recommended that the reader become familiar with these footnotes before studying the list. The inclusion on this list of cases where the cause of death is uncertain or unknown is both valid and consistent with the scientific protocol followed by several other registers of shark attacks compiled elsewhere worldwide, including Australia.

Sixty (57.7 percent) of the 104 cases involve persons who survived the shark attack. For cases occurring during recent years, these individuals have been available to describe the event in detail on a first-hand basis. The circumstances and documentation given by them provide valuable insight that can be used to surmise what may have transpired in fatal cases where no witness was present. For example, read and compare case number 75 with case number 95.

The criteria and style used to compile the list of shark attacks in Hawaii has been patterned after the International Shark Attack File (ISAF), which was first assembled in the late 1950s with funding from the Office of Naval Research. A tabular summary of the ISAF list was published in the 1963 classical reference book entitled *Sharks and Survival,* edited by Dr. Perry Gilbert. Later, in 1973, an analysis of data involving 1,165 cases in the ISAF was published by Dr. David Baldridge in his report "Shark Attack Against Man." The ISAF is currently maintained under the auspices of the American Elasmobranch Society at the Florida Museum of Natural History, with Dr. George H. Burgess as curator. Updated and revised versions of the shark attack list for Hawaii are regularly forwarded by the compiler for inclusion and use by the ISAF.

Cases of shark attack shown in the following list involve some manner of physical injury to the person that resulted from a shark. Cases in which "only" the person's equipment was attacked (bitten), or aggression was displayed without harmful contact to a person, are not included. In this respect, the list for Hawaii is more conservative and differs from certain other lists compiled elsewhere (including the ISAF). On those registers, attacks solely on boats, surfboards and other items are included even though no injury to a human took place. Significant cases of this nature have indeed occurred in Hawaii. At a later date they will be catalogued into a separate list. An example of one such cases is as follows. In October 1990 Greg Filtzer was lying on his nine-foot-long surfboard in Hanalei Bay on Kauai when a twelve-foot tiger shark bit the board and violently pulled it and Greg backwards underwater. In the process the shark ripped off a fourteen-inch-wide piece of the surfboard. Without so much as a scratch, Greg miraculously paddled to shore after the shark released the board. The entire event was witnessed by a companion on a surfboard next to him.

In Dr. Gilbert's book, *Sharks and Survival,* the following notable comment appears on page 466: "Although it is probable that most people would regard a statement of the rarity of attacks in the statistical sense as correct and reasonable, it appears that people in general are less willing to accept a risk involving sharks than greater risks of almost any other kind." This is not surprising, considering that the two words most commonly used in relation to shark attack are "fear" and "apprehension." Most people gain no comfort from being told they are at greater risk from bee stings and car accidents than from shark attack. Statistics alone have a way of reducing people to simple numbers devoid of the personal tragedies and, in some cases, incredible courage associated with shark attack in Hawaii. The following list speaks for itself in that each case presented is an individual story, not simply a statistic.

In the state of Hawaii's 1972 report covering the last systematic shark control and research program conducted in Hawaiian waters, it is stated that "Sharks normally receive negligible fishing pressure and since they function as apex predators in the sea's food pyramid they can increase to maximum density. A dense shark population coupled with growing popularity of water sports activities increase the probability of shark encounters." Although shark attacks are statistically few in number, the validity of this statement now, twenty years later, appears to hold true. There is no question that sharks must be rationally conserved as a fishery resource and not "eradicated" as some have suggested. But at the same time the issue of public safety in Hawaiian waters, coupled with fear and apprehension among residents and tourists alike, must not be neglected.

George H. Balazs
June 1993

## SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS BY ACTIVITY

| Activity | Fatal | Non-Fatal | Total |
|---|---|---|---|
| Swimming/snorkeling | 8 | 15 | 23 |
| Spearfishing while snorkeling | 1 | 5 | 6 |
| Scuba diving | 3 | 1 | 4 |
| Spearfishing while scuba diving | 2 | 0 | 2 |
| Hard hat diving | 0 | 1 | 1 |
| Surfboarding | 2 | 15 | 17 |
| Body (boogie) boarding | 2 | 3 | 5 |
| Sail boarding | 0 | 1 | 1 |
| Body surfing | 1 | 2 | 3 |
| Surfing on an air mattress | 1 | 0 | 1 |
| Floating on an inner tube (w/lobsters) | 0 | 1 | 1 |
| Wading | 0 | 1 | 1 |
| Fell into sea from shore or swept out to sea | 16 | 0 | 16 |
| Fell off boat or boat capsized | 3 | 1 | 4 |
| Net fishing | 0 | 4 | 4 |
| Crabbing | 1 | 2 | 3 |
| Removing shark from fishing line or gaff | 0 | 3 | 3 |
| Dynamite fishing | 1 | 0 | 1 |
| Fishing (type unknown) | 2 | 1 | 3 |
| Activity unknown | 1 | 4 | 5 |
| Total | 44 | 60 | 104 |

## SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS BY SPECIES OF SHARK

| Shark species | No. fatal | No. non-fatal | Total No. cases |
|---|---|---|---|
| Tiger shark | 3 | 6 | 9 |
| Great white | 1 | 1 | 2 |
| Hammerhead | 0 | 2 | 2 |
| Cookie Cutter | 1 | 0 | 1 |
| Subtotal | 5 | 9 | 14 |
| Unknown species, large | 20 | 10 | 30 |
| Unknown species, small | 1 | 8 | 9 |
| Unknown species, unknown size | 18 | 33 | 51 |
| Subtotal | 39 | 51 | 90 |
| Total | 44 | 60 | 104 |

## SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS BY MONTH FOR THE YEARS 1779-1993

| Month | Fatal | Non-Fatal | Total |
|---|---|---|---|
| January | 3 | 2 | 5 |
| February | 2 | 5 | 7 |
| March | 2 | 5 | 7 |
| April | 7 | 9 | 16 |
| May | 2 | 1 | 3 |
| June | 3 | 7 | 10 |
| July | 4 | 2 | 6 |
| August | 4 | 3 | 7 |
| September | 2 | 5 | 7 |
| October | 1 | 6 | 7 |
| November | 4 | 4 | 8 |
| December | 3 | 6 | 9 |

Note: For 92 cases in which the month of attack is known. Cases occurred during the month of April every year for the 6-year period, 1986-1991.

## GENERAL OUTCOME OF SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS, 1779-1993

Compiled by George H. Balazs
(Following categories established by H. D. Baldridge, 1973 in "Shark Attack Against Man")

| | No. of cases | % |
|---|---|---|
| Non-fatal. | 60 | 57.7 |
| Fatal, body or parts thereof recovered, death considered direct result of shark-inflicted wounds. | 10 | 9.6 |
| Fatal, no details reported. | 2 | 1.9 |
| Assumed fatal, body not recovered, no personal gear recovered. | 3 | 3.0 |
| Fatal, body or parts thereof recovered, not known if death was direct result of shark-inflicted wounds. | 17 | 16.3 |
| Fatal, body or parts thereof recovered, death not considered direct result of shark-inflicted wounds. | 9 | 8.6 |
| Assumed fatal, body not recovered, personal gear was recovered. | 3 | 2.9 |
| Total | 104 | 100.0 |

# SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS INVOLVING FATALITIES

| | | | | | Overall | | |
|---|---|---|---|---|---|---|---|
| Years | Direct fatality (a) | Likely direct fatality (b) | Other causes (c) | Cause of fatality Unknown (d) | No. fatal | No. non-fatal | Total no. cases |
| 1990-present | 2 | 3 | 2 | | 7 | 10 | 17 |
| 1980-89 | | 2 | 3 | 4 | 9 | 15 | 24 |
| 1970-79 | | | 1 | 2 | 4 | 8 | 12 |
| 1960-69 | | | 1 | 3 | 3 | 5 | 8 |
| 1950-59 | 3 | | 1 | 3 | 7 | 7 | 14 |
| 1940-49 | | | | 1 | 1 | 5 | 6 |
| 1930-39 | | | | 1 | 1 | 5 | 6 |
| 1920-29 | 1 | | | | 1 | 2 | 3 |
| 1910-19 | | 1 | | 1 | 2 | 1 | 3 |
| 1900-09 | 2 | | 1 | 3 | 6 | 2 | 8 |
| 1779-1899 | 2 | | | 1 | 3 | 0 | 3 |
| Total | 10 | 6 | 9 | 19 | 44 | 60 | 104 |
| | 22.7% | 13.6% | 20.5% | 43.2% | | | |

a = Death directly due to shark attack.
b = Death likely due to shark attack.
c = Death likely due to drowning or other trauma followed by shark attack.
d = Insufficient information upon which to base an opinion as to cause of death.

# ANNOTATED LIST OF SHARK ATTACK CASES IN THE HAWAIIAN ISLANDS 1779 - 1993

(* = FATALITY INVOLVED)

COMPILED BY GEORGE H. BALAZS

HONOLULU LABORATORY, SOUTHWEST FISHERIES SCIENCE CENTER

NATIONAL MARINE FISHERIES SERVICE, NOAA

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 1*[a] | 1779 | Maliu, Hawaii | Nu'u-anu-pa'ahu | Young male gashed on one side of buttocks after being pursued while surf boarding. Subsequently suffered "great pain" and died at Pololu. |
| 2*[a] | 1828 | Lahaina, Maui | Male | "A man out riding surf at 'Uo was killed by a shark which bit off his limbs and left his body floating." Attack witnessed by a number of Hawaiian chiefs. |
| 3*[d] | 2 June 1886 | Hamakua, Hawaii | Two females | Washed into the sea while fishing from shore; one woman found bitten (fatal), the other woman disappeared. |

COMPILER'S OPINION AS TO CAUSE OF FATALITY

[a] Fatality *directly* attributed to shark attack.

[b] Fatality *likely* attributed to shark attack.

[c] Fatality *likely* attributed to another cause (drowning, etc.) besides shark attack which was followed by mutilation or dismemberment by shark or sharks.

[d] *Insufficient information upon which to base an opinion as to cause of death,* although mutilation and/or dismemberment by sharks had occurred. Fatality may have been directly attributed to shark attack, or may have resulted from another cause. This category also includes an absence of any witnesses or the absence of sufficient body remains to determine cause of death by medical autopsy.

| Case No. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 4[*c] | 14 July 1900 | Makapuu Point, Oahu | Emil Uhlbrecht and an unidentified person | Believed to have drowned when carried out to sea while hunting sea shells with companions. "A thorough search was made for the body for several days." Victim's foot with skin and flesh intact "in a fair state of preservation" was found in the stomach of an 11-ft 9-in shark hooked on the night of 8/17/00 off Kakaako, Honolulu, by John Kinipeki. Positive identification of victim made by Mrs. Uhlbrecht, based on an ingrown toe nail. Human pelvis and femur, blackened and totally denuded of flesh, were also recovered from the shark's stomach. These bones were thought to be from a different person, probably one of several Chinese fishermen lost over board in the harbor during past months. |
| 5 | Early 1900's | Inter-Island Dry Dock at Kakaako St. Honolulu | Emil A. Berndt | Young boy severely chafed when a large shark swam between his legs. |
| 6[*a] | 8 Aug. 1902 | Kalihi, Oahu | Young male | Pulled under while crabbing; both arms amputated. |
| 7[*d] | 1904 | Honolulu, Oahu | Male | Partial remains of swimmer who had disappeared two days earlier off Diamond Head found in the stomach of a "monstrous shark." Body was complete from the waist down with the exception of one leg. Shark also contained ducks, tin cans, and wood. |
| 8[*d] | 1907 | Pepeekeo, Honomu, Hawaii | Male | Bitten while fishing. |
| 9 | 8 Oct. 1907 | Kalepolepo, Kihei, Maui | Male | Arm amputated at the elbow while retrieving fish caught in net. |
| 10[*a] | 17 Jan. 1908 | Mana, Kauai | Male | Pulled under while gathering fish stunned by dynamite. |
| 11[*d] | 10 Apr. 1909 | Pauwela, Maui | Mrs. Ah Kim Chong | Nineteen-year old woman reported to have been swept away by waves while gathering opihi along the rocky shore line. Search party saw a large shark |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| | | | | devour what appeared to be part of the missing woman's body. |
| 12 | Apr. 1910 | Pearl Harbor, Oahu | Martin Lund | Unprovoked attack on a hard hat diver. Authenticity questioned. |
| 13[*d] | 1910 | Hilo, Hawaii | Male | Bitten while fishing. |
| 14[*b] | 3 Mar. 1914 | Honomu, Hawaii | Okomoto | Washed into the sea while picking opihi and attacked by two large sharks. |
| 15 | 28 Sept. 1922 | Keawanui, Kamalo, Molokai | Male | Bitten while inspecting wharf. |
| 16 | 7 Apr. 1926 | Hilo Bay, Hawaii | Mrs. Leonard Carlsmith | Severely bitten while swimming 25 yards from shore near the Hilo Yacht Club at 5:30 p.m. "The shark with one bite terribly lacerated her right leg from the heel to the thigh. The calf of her leg was torn nearly to shreds, and the part of her limb above the knee was laid open to the bone." A long necktie was applied as a torniquet to her leg as soon as she was brought to shore. "Anesthetics" were required twice at the hospital in order to treat the wounds. According to the victim, the shark that bit her "had a mouth about three feet wide". |
| 17[*a] | 18 May 1926 | Haleiwa, Oahu | William J. Goins | Gave a sudden shriek then disappeared while swimming at Haleiwa; remains of body found in 12.5-ft great white shark caught off Kahuku. |
| 18 | 13 June 1931 | Pearl Harbor, Oahu | Lieutenant Williamson | End of one of the victim's fingers amputated while using a gaff to bring a 10-ft tiger shark aboard a boat after harpooning it. Shark also bit in half the 2-in oak pole of the gaff. The following items were found in the shark's stomach: hind leg of a mule, two bathing suits nearly digested, soldier's belt buckle, a pint of button's, two horse shoes, corner of a wooden soapbox, anchor chain, two small anchors, and assorted bolts, nails, and copper fittings. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 19*d | 2 Sept. 1931 | Kahala, Oahu | George Gaspar | Swept out to sea by strong currents while fishing; remains of body found in 18-ft shark caught off Barbers Point. |
| 20 | 16 Feb. 1932 | Lahaina, Maui | Male | Sailor from U.S. Navy vessel *Saratoga* bitten while swimming about 1 mile off Mala Wharf. Two wounds each 6-inches long were inflicted. |
| 21 | 4(?) Sept. 1936 | Lahaina, Maui | young male | Leg "badly cut" requiring 19 stitches at the Lahaina Hospital. Swimming with several other children near the "old wharf" when a shark was sighted. Victim disappeared underwater for a few seconds then came to the surface and "made a frantic effort for land". "A large shark was seen again the following morning". |
| 22 | 30 Dec. 1936 | Honokohau, Maui | John Kekuhi | Bitten on the thigh while diving under water trying the retrieve the body of a drowning victim wedged between two rocks. Three deep gashes sustained which required hospitalization. Shark reported to be 20-ft. |
| 23 | 4 Oct. 1939 | Kaneohe Bay, Mokapu, Oahu | James Akina | Bitten on hand by 5-ft shark while spear fishing in shallow water. |
| 24 | 1 July 1941 | Nanakuli, Oahu | Hisao Shimoto | Bitten on arm while removing 100-lb shark from fishing line. |
| 25*d | 5 Apr. 1943 | McGregor Point, Maui | Leonard Gant | Disappeared while swimming with three companions after the small boat they were canoeing swamped in high seas. Swamping occurred three miles from shore. Victim vanished shortly before reaching land after he fell behind the other swimmers. On 4/29/43, the "decomposed remains" of the victim's "right forearm" and "brightly colored swimming trunks" were "found in the stomach of a 16-ft shark" caught in turtle nets set out at night "near the Koa house" by Kihei fisherman Alex Akina. Shark's stomach also contained a piece of newspaper dated 3/25/43. |

|---|---|---|---|---|
| 26 | 1943 | Midway, Northwestern Hawaiian Islands | Male | Unprovoked attack, but unable to determine circumstances. |
| 27 | 1943 | Midway, Northwestern Hawaiian Islands | Male | Unprovoked attack, but unable to determine circumstances. |
| 28 | 27 June 1947 | Makaha, Oahu | Valentine Limatoc | Bitten while spearfishing with six other men. |
| 29 | 19 Sept. 1948 | Makapuu, Oahu | Noah Kalama | Bitten on leg while swimming. |
| 30*[c] | 16 Jan. 1950 | Kahakuloa, Maui | Gilbert S. Hotta | Swept into the sea with two companions by a large sudden wave while fishing at night from the rocky base of an over hanging cliff. Another companion (Wayman Fujimoto) managed to cling to the rocks when the wave hit. The partial remains of Gilbert Hotta were recovered from a "huge shark" caught on the morning of 1/19/50 by rescue workers searching the immediate area. The "badly battered remains" of one of the other missing fishermen (Harold Fujimoto) was also recovered floating nearby. The body of the third fisherman (Hideo Tamura) was never found. |
| 31*[d] | 25 June 1951 | Kapehu Beach, Laupahoehoe, Hawaii | Alejandro Nodura | Swept out to sea while fishing from shore. Victim seen in shark's mouth. |
| 32*[d] | 3 Aug. 1952 | Ala Moana, Oahu | Shigeichi Kawamura | Missing while swimming; shark bite found on right side of body. |
| 33*[a] | 3 Dec. 1952 | Maile, Oahu | Gerbacio Solano | Bitten on arm while swimming from fishing boat; shark reported to be in excess of 22 ft. |
| 34 | 18 Feb. 1953 | Barbers Point, Oahu | James S. Takeuchi | Bitten on hand while removing shark from net. |
| 35 | 4 July 1953 | Kaula Rock | David Crick | Fell off boat while fishing; bitten on leg. |
| 36*[a] | 26 July 1953 | Maile, Oahu | Harold Souza | Bitten on thigh while spearfishing close to shore; 10-ft shark observed. |

| Case no. | Date | Location | Victim | Circumstances |

| 37 | 2 Sept. 1953 | Waiau, Pearl Harbor, Oahu | Daniel Gonsalves | Bitten on leg and foot by 5-ft hammer head shark while crabbing. |
| 38[*d] | 8 Apr. 1954 | Wailupe, Oahu | Gordon S. Chun | Missing while fishing from shore; body recovered in mutilated condition. |
| 39 | 1954 | Molokai | Severino | Unprovoked attack, but unable to determine circumstances. |
| 40 | Apr. 1955 | Hilo, Hawaii | Kanematsu Oshiro | Bitten on hand while fishing from boat. |
| 41 | 20 Sept. 1955 | East Molokai | Phillip C. Diez | Bitten on arm while swimming. |
| 42[*a] | 13 Dec. 1958 | Lanikai, Oahu | William S. Weaver | Leg amputated while surfing on an air mattress near Twin Islands; 15- to 25-ft shark (believed to be tiger shark) observed near body when fire-rescue personnel recovered it 2 hours later. No additional bite marks present on the body. |
| 43 | 1950's | Waikiki, Oahu | David Lloyd | Provoked attack, but unable to determine circumstances. |
| 44 | 27 Feb. 1960 | Makena, Maui | John Benjamin | Severe lacerations obtained while spearfishing. |
| 45[*d] | 27 Dec. 1960 | Maile Point, Oahu | Harold Riley | Swept out to sea while net fishing; 20-ft shark observed attacking victim; body recovered off Nanakuli. |
| 46 | 2 Aug. 1961 | Pearl Harbor, Oahu | Kazuhiko Kato | Bitten on hand by 8-ft shark while net fishing. |
| 47[*d] | 8 Apr. 1963 | Hapuna Beach, Hawaii | Roy C. Kametani | Washed into the sea while picking opihi; parts of body recovered. |
| 48 | 12 Apr. 1963 | Awili, South Kona, Hawaii | Aiona Aka | Bitten on leg and foot while surfing; 12- to 15-ft shark observed. |
| 49[*d] | 20 Sept. 1967 | Kailua Bay, Oahu | Male | Victim lost at sea when boat capsized between Oahu and Molokai; remains of body found in 11-ft tiger shark. |
| 50 | 9 Mar. 1969 | Makaha, Oahu | Licius Lee | Bitten on leg while surfing; identified as great white shark based on teeth marks in surfboard; dead whale recently removed from the area. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 51 | 11 Nov. 1969 | Barbers Point, Oahu | D. R. McGinnis | Bitten on tank while scuba diving for lobsters; abrasions on arms and legs and cut on ankle resulting from contact with shark. |
| 52[*c] | 31 Mar. 1970 | Waimea Bay, Oahu | Ernie Reathaford | Swept out to sea while body surfing; 15- to 18-ft shark observed. |
| 53 | 24 Oct 1970 | Brennecke Beach, Poipu, Kauai | James C. Mattan | Bitten on shoulder and arm while body surfing. |
| 54 | 16 Mar. 1972 | Waihee, Wailuku, Maui | Adam Gomes, Jr. | Bitten on leg while spearfishing. |
| 55 | 17 Aug. 1972 | Waimanu, Honokaa, Hawaii | Eric Fotherby | Bitten on arm by 8-ft shark while spearfishing. |
| 56 | 9 Jan. 1973 | Hookipa Beach, Paia, Maui | Robert Sterling | Bitten on leg while surfboarding close to shore; 4 to 6-ft shark observed in area: wound required 100 stitches. |
| 57 | 18 Dec. 1973 | Kalama Beach, Kihei, Maui | Gary W. Floyd | Bitten on leg while swimming close to shore. |
| 58 | 10 June 1976 | Kamaole Beach, Park No. 1, Kihei, Maui | Donald Gard | Bitten on foot and leg by 3- to 5-ft shark while swimming. |
| 59[*d] | 16 July 1976 | Mahaulepu, Koloa, Kauai | Stephen C. Powell | Missing while scuba diving; lower remains of body recovered. |
| 60[*c] | 1976 | Off Lahaina, Maui | Danson Nakaima | Apparently passed out while scuba diving for black coral at a depth of 180 ft. About 30 large sharks seen near partially devoured remains of the body. |
| 61 | 21 Apr. 1977 | Kaanapali, Maui | Ruskin Vest | Bitten on arm by 4-ft. shark while swimming close to shore. |
| 62 | 27 Nov. 1978 | Ewa, Oahu | Wendell Cabunoc | Severely bitten on arm while surfboarding; 8-ft shark observed. |
| 63[*d] | 1979(?) | South Kohala, Hawaii | Elderly male | Disappeared while fishing from shore. Fire Department divers only found a hand and a flashlight. Note: No known literature documentation. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 64 | 4 Aug. 1980 | Puamana, Lahaina, Maui | Mark Skidgel | Bitten on left side of body while resting on a body board 40 ft from shore; identified as 14-ft tiger shark; wound required 52 stitches. |
| 65*[d] | 24 May 1981 | Haena Beach Park, Kauai | Roger B. Garletts | Missing while scuba diving at a depth of 60- to 80-ft; only diving equipment recovered, including shredded wet suit bearing numerous tooth marks. Victim reportedly spearfishing in murky, choppy water. |
| 66*[c] | 12 June 1981 | Honolii Pali, Hilo Bay, (Alae Point), Hawaii | Preston D. Soley | Retrieval of floating body hindered by 4-ft shark. Autopsy showed that death was probably from drowning. One-third of body missing due to bites by at least four sharks. |
| 67*[d] | 24 Aug. 1981 | Keaukaha, Hilo, Hawaii | Ernest Watson | Disappeared while fishing from shore. Leg found 7 days later wedged in rocks 150 yd offshore. |
| 68 | 9 Nov. 1981 | Laau Point, Molokai | Leo A. Ohai | Bitten on hand while untangling crab-trap line from propellor. Seven-foot shark had followed the boat for 3 days and reportedly was very unusual looking with a "flat head". |
| 69 | 13 Dec. 1981 | Nimitz Beach, Barbers Point, Oahu | Melvin T. Toma | Severely bitten on right leg by 12-ft tiger shark while swimming at the surface shortly after entering water; site located 300-400 yd from shore over a depth of 20 ft. Looking for fish, but none had been speared when attack occurred; wound required 200 stitches. |
| 70 | 14 Feb. 1982 | White Plains Beach, Barbers Point, Oahu | Lisa Miller | Bitten on left leg while wading in 3 to 4-ft of water; 17 stitches required. |
| 71 | 14 Feb. 1982 | White Plains Beach, Barbers Point, Oahu | Female | Bitten on right foot while swimming in shallow water. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 72 | 13 June 1982 | Hookipa Beach, Paia, Maui | Scott Shoemaker | Severely bitten three times on the thigh after falling into water while sailboarding 100 yd outside the breakers. Wounds required 120 stitches. |
| 73 | 3 June 1984 | Kaneohe Bay, Oahu | Susan Buecher | Bitten on the foot while towing her sister on a plastic ski board. Incident happened at 5 p.m. in water 5-ft deep, about 400 yd from shore. Surgery and lower leg cast required to repair damaged tendons. 4-5 ft hammerhead shark believed to have been responsible. |
| 74 | 12 Oct. 1985 | Barbers Point, Oahu | Dominic Dela Cruz | Severe gashes to left arm requiring surgery. Attack occurred off Barbers Point Lighthouse while floating on an inner tube after diving for lobster. |
| 75 | 18 Oct. 1985 | Princeville, Kauai | Joe Thompson | Right hand and portion of forearm amputated by a large shark (likely a tiger shark) while body-boarding. Gash sustained to left hand. Right anterior side of board also cut away during same bite by shark. |
| 76*[c] | 20 Apr. 1986 | Kalihiwai, Kauai | Levi Chandler | Fell from rocks and disappeared while fishing at Kalihiwai Point. Pieces of clothing and human flesh were recovered by Fire Department divers who encountered a large shark. |
| 77*[b] | 15 Apr. 1987 | Kailua-Kona, Hawaii | Daniel Kennedy | Last seen swimming from shore out to an anchored sailboat. Swimming trunks found bitten in half on the bottom. |
| 78 | 25 Mar. 1988 | Running Waters Beach, Ninini Point, Kauai | Aaron Kawado | Bitten on the ankle while body surfing in waist-deep water. Surgery required to repair severed vein. |
| 79*[d] | 15 Apr. 1988 | Waihee, Maui | Avery Goo | Lost at sea when the 21-ft powerboat he was on capsized in rough seas. Pieces of human stomach, intestines, and pancreas believed to be from victim found several days later washed ashore along the Waihee shoreline. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 80*[d] | 8 Jan. 1989 | Wailua, Kauai | Ken Ahlstrand | Disappeared while swimming in strong current with three other people. A 2-day search by helicopters, Civil Air Patrol, and firemen failed to find any trace of the missing man. Lower part of body found 6 days later on 1/14/89 near seawall by the Wailua Golf Course. X-rays of remains revealed teeth marks in femur and tibia. |
| 81 | 20 Jan. 1989 | Waialua Beach, Molokai | Earl Dunnam | Ten-year-old boy bitten on the foot by a 6-8 ft hammerhead shark while riding a body board 200 ft from shore. Wound required 8 stitches. Bite occurred to a naked foot, and not to the foot wearing a swim fin. Note: No known literature documentation. |
| 82 | 3 Apr. 1989 | Hookipa Beach, Paia, Maui | Sam McLain | Sustained a 4-in long crescent-shaped wound on the calf while paddling on a surfboard in whitewater near rocks 50 yards from shore. A sharp "tug" was felt at the time of injury. 13 stitches were used to close the wound. |
| 83 | Apr. 1989 | Kekaha Beach, Kauai | William P. Allen | "Tremendous impact" felt on left leg while paddling on a surfboard in glassy water just beyond swells. Impact lifted board and surfer 2-3 ft out of the water. Left thigh raked with a series of scratches believed to have been caused by teeth. Skegs on the board were knocked loose, and a strip of fiberglass 8-in wide by 5-ft long was torn off. Victim convinced he was attacked by a "huge shark". |
| 84 | 29 June 1989 | Anahola, Kauai | Anthony Paden | Severely bitten on the foot after falling off a surfboard about 20 ft from shore. A "big chunk" taken out of victim's ankle, and "bite marks" inflicted all around the foot. Achilles tendon was half-severed, requiring surgery and a cast. |
| 85*[b] | 14 Oct. 1989 | Kahe Point, Oahu | Ray Mehl, Jr. | Abruptly disappeared while scuba diving as a novice with his partner at a |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| | | | | depth of 27 ft, 750 ft from shore near the cooling water discharge pipe of the Kahe Point Power Plant. Unusual behavior exhibited by parrotfish just prior to disappearance. Victim was 10-15 min into the dive with nearly a full tank of air. Dive partner conducted a circle search, but could not locate victim. Time of event was 4:30 p.m., visibility 25-30 ft. Decapitated body with amputated left arm found 200 ft to the west by fire rescue divers the following morning. Large tiger shark suddenly appeared and proceeded to consume rest of body before rescue divers could retrieve it. Small piece of flesh and some dive equipment later recovered. |
| 86*[c] | 12 Nov. 1989 | Ehukai Beach Park, Sunset Beach, Oahu | Edward Malek | Knocked down and swept away by large waves while wading close to shore at 6 p.m. Lower portion of body, sheared at waistline, recovered by fire rescue personnel on the morning of 11/15/89, 1.5 miles to the southwest. Note: The rare sighting of a shark was made at Ehukai Beach Park on 11/5/89, at which time all swimmers were cleared from the ocean for an hour. |
| 87 | 19 Dec. 1989 | 90 miles east of Hilo, Hawaii | George Sohswel | Crew member of the 51-foot fishing vessel One Ki sustained a 23-cm long bite on his left leg and four 7-cm lacerations to left foot. 3 days hospitalization required. Victim transported to Hilo by Coast Guard helicopter. Wound was inflicted by a shark brought aboard the vessel. |
| 88*[b] | 17 Feb. 1990 | Mokapu, Kaneohe Marine Corps Air Station, Oahu | Roy T. Tanaka | Failed to return with his partner (Jake Hernandez) while scuba diving and spearing parrotfish in water 40-ft deep, 200 yards from shore (near firing range) at 9:30 p.m. 22-ft boat nearby had overturned a short time earlier after being hit broadside by a wave. Victim's tank, backpack, dive light, and mask were found on the bottom but not |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| | | | | retrieved. Body with amputated right arm sighted from helicopter at 3 p.m. 2/18/90 between Makai Pier and Rabbit Island. Two sharks (8 and 14 ft) seen nearby. Larger shark, apparently reacting to the presence of the helicopter, proceeded to consume all but torso and legs before retrieval. |
| 89 | 1 Apr. 1990 | Silver (Silva) Channels, Waialua Oahu | Everett Peacock | Deep abrasion causing profuse bleeding inflicted to 10-in area on lower left leg while sitting on a surfboard. Also sustained two deep 3-in long gashes above left ankle. Event occurred before 7:30 a.m. in murky water 150 yds from shore. |
| 90 | 3 Apr. 1991 | Oneula Beach Park, Ewa Beach, Oahu | Todd R. Wenke | Bitten on the left leg and foot while sitting on a surfboard 350 yards from shore at 5:30 p.m. at a site known as "Shark Country" 1/4-mile east of Oneula Beach Park. Attack resulted in a 5-in long bone-deep wound on each side of the foot, and a 9-in long bone-deep wound on the calf. 30 stitches, tendon surgery, and a cast required. Only about 18 inches of the shark's head was seen and no positive identification was possible. Shark had "a very large girth." |
| 91 | 26 May 1991 | Maili Beach, Oahu | Frank (Scott) Betz | Bitten on the right calf while sitting on a surfboard 100 yards from shore at 4:45 p.m. Attack resulted in 4-in and a 7-in long wound requiring stitches. Shark estimated to be 8-ft long. Event occurred in murky water. |
| 92*[b] | 19 Nov. 1991 | Maliko Point, Maui | Suk Kyu (Steve) Park | Swept into the sea by a large wave while fishing from the rocky coastline at 4:30 p.m. Victim's son went for help shortly thereafter when it became apparent that surf conditions were too rough for his father to swim ashore. When last seen victim was treading water signaling the son to go for assistance. Help arrived about 30 min later, but no sign of the victim could be found. Victim's shorts |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| | | | | and shirt were recovered from the ocean bottom the following morning by fire rescue divers. Both garments had large portions missing on the left side. Bite marks present were consistent with attack by a 12-ft tiger shark. Note: Victim was reported to be a strong swimmer in good physical condition. |
| 93*[a] | 26 Nov. 1991 | Olowalu, Maui | Martha J. Morrell | Snorkeling with a female companion at 9 a.m. near reef edge in partly cloudy water 10-15 ft deep about 100 yards from shore, and 50 yards from the end of an old pier next to the victim's beachfront home. An 8- to 11-ft shark passed by the companion and proceeded to attack the victim, initially on the right arm. A small boat was used to recover the body a short time later. Amputations included the victim's right leg at the hip joint, the left leg sheared through the femoral neck, the right forearm, as well as numerous bites and tissue loss elsewhere. |
| 94 | 26 Nov. 1991 | Olowalu, Maui | Louise Sourisseau | Snorkeling companion to Martha J. Morrell (see Case No. 93). Abrasion to right calf when large shark rubbed against her in association with fatal attack on Mrs. Morrell. Following the initial attack on Mrs. Morrell the shark estimated to be 8-11 ft, swam slowly under Louise Sourisseau who assumed a motionless position floating on her back. When first seen prior to the attack, the shark was coming from a seaward direction. No other significant marine life was observed in the vicinity prior to or after the attack. |
| 95*[b] | 19 Feb. 1992 | Leftovers, near Waimea Bay, Oahu | Bryan Adona | Disappeared while body-boarding late in the afternoon at a surfing site about 1.2 mile southwest of Waimea Bay (near 61-350 Kam Highway). The following morning, 2/20/92, his board was found washed ashore at Waimea Bay with a 16-in crescent-shaped piece missing from |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| | | | | the anterior left side. Distinct serrations of shark bite were present in board and severed segments of rubber leash still attached to board. Danny Titilah, the last person to see Bryan Adona alive, saw a large shark shortly after he and Adona paddled out toward separate breaks at Leftovers. Others on shore also reported seeing a large shark in the vicinity. Left swim fin, identified as Bryan Adona's, was subsequently found during an extensive search. Strap of fin was severed, but without serrations. |
| 96 | 28 Mar. 1992 | Cannons, Haena, Kauai | Jude Chamberlain | Scratches and small puncture inflicted to foot when a large shark bit her surf board while paddling seaward 10 ft from reef edge (and 85 ft from shore) in clean water about 10 ft deep. 12-14 in. crescent bite marks made in both sides of board. Shark shook board three times then pulled it completely under water and dragged victim by leash for 20 ft before leash severed and shark released surf board. Attack occurred at about 6:45 a.m. after victim had been surfing there for a short time with a friend (Mike Cox), who witnessed the attack at close range. |
| 97*[c] | 23 July 1992 | Waianae, Oahu | Zosimo Popa | Victim and his son (Jeffrey Popa) failed to return from an overnight fishing trip in a 14 ft. boat. Body was found 7/23/92 tied to an ice chest floating 15 miles off the Waianae coast. Victim had sustained two cookie cutter shark bites to the lower back. Wounds were 2 inches in diameter by 1.5 inches deep and were "probably post mortem." Cause of death was "asphyxia by drowning." Life jackets and debris were recovered in the vicinity, but victim's son and the boat were never found. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 98*[c] | 21 Aug. 1992 | Twin Arches, Hana Ranch, Maui | Chester N. Shishido | Fell from a cliff while fishing and disappeared in strong current. Rescue efforts were immediately made by the victim's brother and, 30 min. later at 2:30 p.m., by helicopter and a fire rescue unit. No trace of victim was seen and the search was stopped at 5:30 p.m. Body was recovered the following morning (8/22) 200 yards from shore at a depth of 65 ft. Amputations included the left arm, right hand fractured at the wrist, as well as other numerous lacerations and tissue loss consistent with shark bites that "appeared to be post mortem." |
| 99 | 22 Oct. 1992 | Laniakea, Oahu | Eric Gruzinsky | Bruises and scratches to underarm and chest resulting from a 10-12 ft. shark biting a crescent-shaped piece from victim's 6 ft. 4 in. surfboard. Attack occurred at 7:50 a.m. in clear water 15 ft. deep 150 yards from shore. |
| 100*[a] | 5 Nov. 1992 | Keaau Beach Park, Oahu | Aaron A. Romento | Severely bitten in three places on the right leg by a 10-12 ft. shark. Victim was body-boarding at 9:45 a.m. in clear shallow water 30 yards from shore. Death resulted from blood loss and shock a short time after the victim paddled ashore. Wounds did not involve the removal of tissue. |
| 101 | 23 Dec. 1992 | Chun's Reef, Oahu | Gary M. Chun | Cuts to left hand resulting from 10-12 ft. shark biting a 15 in. crescent-shaped piece from victim's surfboard. Attack occurred at 5:30 p.m. while lying on surfboard 100 yards from shore in the presence of 20 or more other surfers. Victim was surfing "near a channel where the current flows like a river through a break in the reef." |
| 102 | 28 Dec. 1992 | Honomuni, Molokai | Pahu Tanaka | Abrasion and bruise to right leg of 10-year old boy inflicted by 8-ft tiger shark. Victim was standing 50 yards from shore in waist-deep water in the morning helping his father tend a gill net containing dead fish. |

| Case no. | Date | Location | Victim | Circumstances |
|---|---|---|---|---|
| 103 | 14 Mar. 1993 | Wailuaiki Bay, Maui | Roddy P. Lewis | Severely bitten on the legs by a 12-14 ft. shark while paddling on a 7 ft. 4 in. surfboard at 3:45 p.m. about 100 feet from shore near a river mouth. Shark shook victim but let him go after he punched it on the side of the head. Victim's lower right leg sustained a 14.5 in. gaping cut on the inside, and a 13 in. one on the outside, requiring 145 staples and an unknown number of internal sutures. Left leg sustained a 4 in. cut needing 7 staples. Five separate surgeries were needed to repair tissue damage. Fragment of tiger shark tooth removed from victim's leg bone. Only two other surfers were in the vicinity when the attack occurred. Water visibility estimated to be 5 feet. |
| 104 | 10 June 1993 | Malaekahana State Recreation Area, Laie, Oahu | Jonathan Mozo | Bitten on the feet while paddling on a 6 ft. surfboard in shallow water at 7:10 a.m. 100 yards from Goat Island (Mokuauia). When attack occurred, victim looked back and saw a large shark with its mouth wide open. Victim raised up his legs and paddled to shore as fast as possible. Numerous lacerations sustained requiring 30 stitches to each foot. Victim's companion (Ryan Bell) was on a body board nearby and felt something bump him shortly before the attack. Victim and companion were the only people in the water at the time. |

# Marine Turtle Faeces on Hawaiian Beaches

GEORGE H. BALAZS*, ROGER FUJIOKA† and CARRIE FUJIOKA†
**Honolulu Laboratory, Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA, 2570 Dole Street, Honolulu, HI 96822-2396, USA*
*† Water Resources Research Center, University of Hawaii at Manoa, 2540 Dole Street, Honolulu, HI 96822, USA*

**Faeces of the green turtle, *Chelonia mydas*, washed ashore in large numbers at a beach park in Hawaii over a 40-day period in 1989. The formed pellets were originally misidentified as being from pigs or humans, and therefore were perceived as a pollutant of potential health hazard to humans. However, bacteriological analysis of the nearshore waters indicated low and legally acceptable levels of faecal coliforms and enterococci. Similar diminished levels were also found in direct cultures of the fresh pellets. Green turtle faeces have been known to drift ashore in Hawaii, but never in the quantities recorded during this short-term event. The reason for the occurrence could not be determined, but several possible explanations are given.**

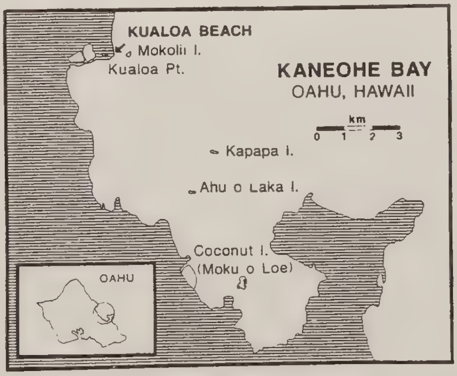

**Fig. 1** Location of Kualoa Beach (21°31′N, 158°51′W) where faeces of the green turtle washed ashore in record numbers during 1989. Kaneohe Bay, the largest bay in the Hawaiian Islands, is 13 km long and 4 km wide.

During July of 1989, numerous floating faecal pellets began to wash ashore on the island of Oahu at Kualoa Beach Park located at the northwestern end of Kaneohe Bay, the largest bay in the Hawaiian Islands (Fig. 1). As a precautionary measure, the State of Hawaii's Department of Health closed this 1 km stretch of beach to public use. At the same time an effort was made to determine the source of the pellets and their possible health hazards. Sewage spills into Hawaii's nearshore waters from treatment plants have been reported but have never resulted in the appearance of formed faeces in the water. No spills of this nature occurred at the time. Faecal wastes from domestic pigs being transported by barge were initially suspected. The possibility of a human origin from tourist-related recreational activities was also suggested by the news media, but this was unlikely. Coliform counts in surrounding waters, however, were not elevated (Fig. 2) as might be expected in such cases.

A more careful investigation of the droppings revealed them to be faeces originating from the herbivorous green turtle, *Chelonia mydas*. The pellets ranged from 0.5 to 2 cm in diameter and up to 5 cm long (Fig. 3). They were found to consist almost entirely of partially digested benthic algae, mainly *Codium edule* and *Amansia glomerata*, which are commonly eaten by green turtles in Hawaii. Algal particles were clearly discernible with the naked eye after the pellets were broken open. In addition, ova in the faeces were determined to be from non-mammalian parasites, and most likely from flukes that parasitize green turtles in Hawaii (Dailey *et al.*, 1991). The pellets were green to brownish in colour and 'dog-like' in appearance. They had a distinctly different and somewhat less objectionable odour than mammalian faeces, and appeared to be less attractive to flies and other insects.

Kualoa Beach was reopened after a 40-day closure (11 August–22 September 1989) when the daily number of pellets declined and any health risks to humans were judged to be minimal (Fig. 4). During the

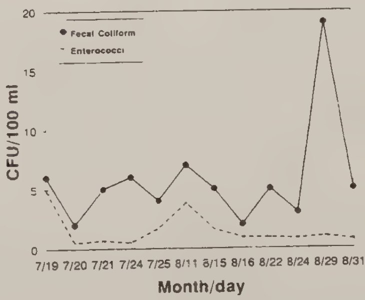

**Fig. 2** Faecal coliform and enterococci counts (Colony Forming Units (CFU) per 100 ml) in the nearshore waters at Kualoa Beach, 19 July to 31 August, 1989, sampled while green turtle pellets were washing ashore.

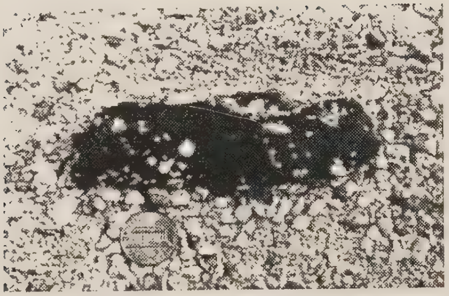

Fig. 3 Faecal pellet of a green turtle washed ashore at Kualoa Beach.

periods of greatest abundance, over 300 pellets per day (maximum 470 pellets) were counted and picked up for disposal by park maintenance personnel. A total of nearly 5500 pellets were removed during the 40 days. Even after the beach was reopened, pellets continued to float ashore, but in much reduced numbers.

## Bacteriological Analyses

Despite the high abundance of faecal pellets seen during the 40 days, nearshore water samples analysed by the Department of Health did not exceed indicator bacterial limits set by the US Environmental Protection Agency for ocean recreational waters (i.e. <33 Colony Forming Units of faecal enterococci per 100 ml of sea water, Fig. 2). Spills from sewage treatment plants have on occasion produced counts in Kaneohe Bay of up to 2300 CFU of faecal coliform and 570 CFU of enterococci (State of Hawaii, Department of Health, pers. comm.).

To measure bacteriological aspects of the turtle faeces, a preliminary follow-up study was conducted. Faecal coliforms and faecal enterococci from turtle pellets freshly collected at Kualoa were found to be low (most probable number (MPN) 3–43 $g^{-1}$ of faeces), compared with mammalian and avian faeces (MPN $10^6$–$10^8$ $g^{-1}$ of faeces). Furthermore, turtle pellets held at laboratory room temperature (21.5–25.5°C) showed no multiplication of faecal coliforms or enterococci. Pellets placed in beakers of seawater for 15 days continued to remain intact, and mostly buoyant, with no bacterial growth. Breaking the faeces into small pieces after 15 days failed to result in the isolation of faecal coliforms or enterococci (Fujioka, 1990). Cultures from fresh pellets performed by a private hospital laboratory, as well as the State of Hawaii's Department of Agriculture, were found to be negative for Salmonella.

## Results and Discussion

Faecal pellets of the green turtle have been known since 1976 to occasionally wash ashore in small numbers on certain beaches throughout the Hawaiian Islands. The opportunity to easily collect this material has provided a simple method of identifying food sources exploited by the turtles in their nearshore foraging pastures (Balazs, 1980). However, Kualoa is not a site where this phenomenon had been previously reported. Park maintenance personnel, lifeguards, and other people long familiar with Kualoa Beach unanimously agreed that large numbers of faeces have never washed ashore there.

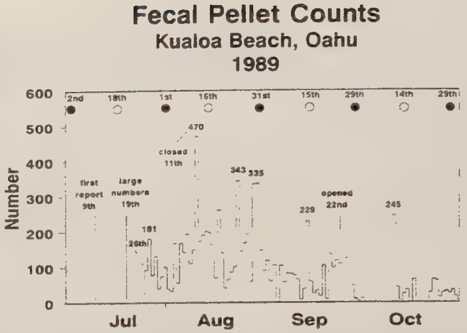

Fig. 4 Green turtle faecal pellet counts at Kualoa Beach, July–October 1989. The State of Hawaii's Department of Health closed the beach to public use from 11 August–22 September, 1989.

No unusual seasonal weather conditions, nor notable activity by turtles immediately off Kualoa, occurred that might explain the observed faecal event. A general review of data for tidal cycles, moon phases, wind speed and direction, and surf conditions failed to identify any consistent correlation with the erratic fluctuations in daily faecal counts recorded (Fig. 4). Southeasterly winds prevailed on 28–29 August 1989, which partly coincided with counts of 335 pellets per day ashore for 2 days in a row. However, no such relationship was apparent for any of the other days studied. It should be noted that green turtles are only occasionally sighted directly off Kualoa, where they sometimes become entangled in fishing lines or wash ashore dead from various causes.

The most plausible area for the faecal pellets to have originated appears to be Kaneohe Bay, which extends for some 13 km immediately to the southeast of Kualoa Beach (Fig. 1). A comparatively large aggregation of green turtles, estimated at 500 or more individuals mainly composed of immature size classes resides in this bay for foraging and resting purposes. There is no evidence that a sudden increase in turtles occurred during 1989 (or in any other year). However, for the past 4 years, special attention has been focused on the turtles in Kaneohe Bay because of the documented increased incidence of fibropapillomas, a debilitating and life threatening tumour disease of unknown aetiology. About 50% of all green turtles found washed ashore in a dead or disabled condition in the Hawaiian Islands have these tumours (Balazs & Pooley, 1991). In addition, about half of the turtles sighted during diving surveys in Kaneohe Bay now have these tumours to varying degrees of severity.

The possibility exists that the large quantity of faeces that washed up on Kualoa Beach during the summer of 1989 may have been related in some way to the tumour epidemic in Kaneohe Bay. However, the manner in which this might have been mediated remains unknown.

and open to speculation. Perhaps a sudden surge of the disease reduced the turtles' ability to adequately digest algae, possibly by changes in intestinal microbes, thereby causing the faecal pellets to be more buoyant and resistant to breakdown. It is known that many, and possibly most, faecal pellets from Hawaiian green turtles are not buoyant but rather sink to the bottom, and hence never wash ashore.

Another hypothesis is that certain turtles feeding exclusively on *Halophila hawaiiana*, a sea grass that grows in Kaneohe Bay, moved to algal foraging habitats during the summer of 1989. Bjorndal (1980) has pointed out that a change of diet by the green turtle, from sea grass to one of algae, would likely require radical changes in intestinal microflora resulting in a lowered digestive efficiency, at least for a period of time. Such a move could have been related to the tumours and/or the considerable increase in commercial tourist-related activities and associated disturbances to foraging turtles in the bay. Since 1989, certain sections of Kaneohe Bay where turtles forage heavily on *Halophila* have been legally set aside as zones that exclude anchoring by commercial tour operators.

Kualoa Beach has been periodically monitored for a reoccurrence of the mass arrival of faecal pellets since late 1989. Such an event has not been seen again, although small numbers continue to wash ashore both at Kualoa and elsewhere in Hawaii. Even at low levels, the drifting ashore of these faeces appears to be unique. No other published or even anecdotal reports are known of faecal pellets of the green turtle, or any other species of marine turtle, washing up at any location outside of the Hawaiian Islands.

# AN EXPERIMENTAL AERIAL SURVEY FOR VAQUITA (*PHOCOENA SINUS*) IN THE NORTHERN GULF OF CALIFORNIA, MEXICO

The vaquita (*Phocoena sinus*) is endemic to the Gulf of California and all recent sightings have been in the northern Gulf (Silber 1990*a, b*) where most survey efforts for this species have been concentrated. Previous ship surveys for this species were conducted by Villa-R. (1976), Wells *et al.* (1981), Vidal *et al.* (1987), and Silber (1990*b*) (Table 1). Aerial surveys were also conducted by Silber (1990*b*) and Silber and Norris (1991). None of these surveys produced quantitative estimates of vaquita population size. We conducted an experimental aerial survey in the northern Gulf of California from 11 to 14 September 1991 to evaluate the feasibility of using aerial census methods to estimate vaquita population size.

The line-transect methods and aircraft used in this experimental work were the same as were used in quantitative surveys of harbor porpoise (*Phocoena phocoena*) in California (Forney *et al.* 1991). The aircraft was a twin-engine Partenavia P-68 fitted with bubble windows on each side and a 20 × 30-cm viewing port in the belly of the aircraft. Direct downward visibility was possible from all three observer positions. Surveys were flown at an airspeed of 166 km/h and an altitude of 183 m. Transects were established on a uniform grid at 22.2 km spacing (Fig. 1). The starting point of the grid was chosen arbitrarily as the intersection of latitude 30°45′N with the eastern shoreline of the Gulf. The initial survey design included only areas north of 30°45′N (which enclosed the area of all confirmed sightings reported by Silber [1990*b*]). Survey lines were added in shallow waters immediately south of the primary grid along the western shoreline of the Gulf after hearing a report by local fishermen of vaquita

*Table 1.* Scientifically documented sighting history for vaquitas in the Gulf of California. Effort indicates the number of transect km surveyed (by boat unless noted otherwise). Caveats on identification expressed by the author are given below the source citation.

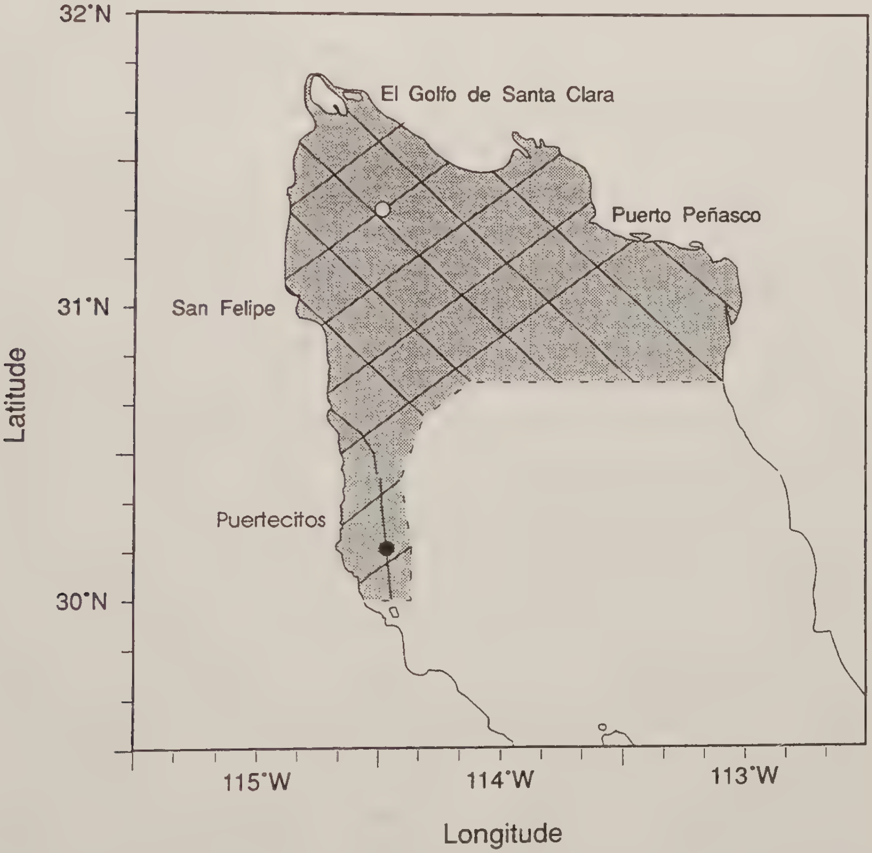

*Figure 1.* Survey transect lines flown in the northern Gulf of California during the experimental aerial survey for vaquitas. The lower (southernmost) solid circle indicates the position of the only confirmed sighting of vaquitas. The upper open circle indicates the position of a probable sighting.

being in that area in September. All transects were flown towards the northwest in the mornings and towards the northeast in the afternoons to minimize sun glare. Observers consisted of the four authors, who rotated among four positions. Two of the observers (J.B. and K.A.F.) have extensive experience (>3 yr) conducting similar aerial surveys for *Phocoena phocoena*. The primary observer team consisted of left (seated behind pilot), right (seated behind recorder), and belly (lying down in rear of aircraft and viewing through the belly port) positions. The fourth position was data recorder (in the co-pilot seat). The pilot and data recorder were instructed not to mention cetacean sightings until after they had passed out of the field of view of the primary observation team. The perpendicular distance from the transect line to any observed marine mammal was calculated from altitude and declination angle measured using hand-held clinometers. The width of the search path was unbounded, but observers were told to concentrate their efforts close to the trackline. Information on changes in sea state and viewing conditions were recorded immediately on a lap-top computer which was linked to aerial navigation instruments. Position was determined by LORAN which had been calibrated using a GPS satellite navigation device.

A total of 1,143 km was completed on aerial transect lines during 3.5 d of surveying. Two transect lines in the southeast (not shown in Fig. 1) were not completed due to insufficient time. All transects were completed under clear skies and with Beaufort sea state conditions of 0–1 (155 km), 2 (503 km), 3 (472 km), or 4 (13 km). Only one sighting of two vaquita was made by the primary survey team. Another probable sighting of one vaquita was made by the data recorder. [Sightings made by the data recorder are typically not used in harbor porpoise population estimates because the fraction of time they are actively searching is difficult to quantify (Barlow *et al.* 1988).] Other species seen included common dolphins (*Delphinus delphis*), bottlenose dolphins (*Tursiops truncatus*), false killer whales (*Pseudorca crassidens*), fin whales (*Balaenoptera physalus*), minke whales (*Balaenoptera acutorostrata*), and California sea lions (*Zalophus californianus*).

The only certain vaquita sighting was made south of San Felipe, Baja California Norte, under clear skies, with Beaufort 1, and in relatively clear waters (Fig. 1). Two vaquitas were traveling rapidly approximately 2 m under the surface, breathing relatively infrequently in the characteristic "pop-splash" of rapidly moving harbor porpoise (Taylor and Dawson 1984). All observers obtained a good view of these animals while the aircraft circled. The other, "probable" sighting occurred in the region north of Rocas Consag where vaquitas have been most frequently reported (Silber 1990*b*) (Fig. 1). That sighting occurred in very turbid waters by only one person for less than 1 sec. The animal surfaced once and dived straight down, disappearing within 1 m of the surface due to the turbid conditions. Based on extensive experience on harbor porpoise aerial surveys, the data recorder (K.A.F.) classified that animal as a probable *Phocoena*.

Clearly, insufficient sightings were made to make a reliable line-transect estimate of vaquita population size from this survey. However, it is clear that vaquita were relatively scarce in our study area. Both *Tursiops* and *Delphinus* were seen more frequently. The sighting rate for vaquitas was 1.8 per 1,000 linear km surveyed (or 2.6 per 1,000 km including the "probable" sighting). This is lower than sighting rates on previous aerial surveys which concentrated effort in areas of presumed high density: 7.2 vaquitas per 1,000 km (Silber 1990*b*) and 7.0 per 1,000 km (Silber and Norris 1991). In contrast, 47.0 harbor porpoise per 1,000 km were seen on systematic aerial surveys in central California (Forney *et al.* 1991).

Although this study and others (Silber 1990*b*, Silber and Norris 1991) have shown that vaquitas can be seen from aircraft, quantitative aerial surveys for this species are plagued by difficulties and uncertainties. From the sighting rate of this survey, it is clear that a much larger-scale survey is needed for reliable population estimates. A sample size of 100 sightings is desirable to allow stratification by Beaufort sea state and cloud cover, factors that have been shown to be important in harbor porpoise aerial surveys (Forney *et al.* 1991). This would require a great amount of effort, and a synoptic survey of this magnitude would require the coordinated work of several aircraft. Another major impediment is the difficulty in quantifying the fraction of animals that are visible from the air. A simple line transect estimate only represents the number visible from the air at any given moment. For harbor porpoise seen in relatively clear waters in California, a correction factor of 3.2 has been used to account for submerged animals that would not be visible from the air (Barlow *et al.* 1988). A correction factor for submerged animals is likely to depend on water turbidity. Turbidity in the northern Gulf of California is typically much greater than in California and is influenced by tides and by sediment transport from the Colorado River. Turbidity in the Gulf changes markedly over very short distances. Not only would several correction factors be needed for different water turbidities, but also some method would be needed to accurately quantify turbidity during aerial surveys. Uncertainty in estimating these (probably large) correction factors would add considerable uncertainty to quantitative estimates of population size. Future aerial surveys should be preceded by studies of the fraction of time vaquitas are visible from the air, perhaps using the type of helicopter experiment that was used to obtain these data for harbor porpoise (Barlow *et al.* 1988).

Turbidity and fraction of time spent at the surface are less of a problem for ship than for aerial surveys. Although cetaceans are typically seen from ships only when some part of the animal is above the surface, surface vessels travel relatively slowly and most animals will surface at least once within the visual range of the ship. Given the difficulty and uncertainty in estimating the large correction factors for submerged animals on aerial surveys, effort might be better allocated to large-scale ship surveys.

## Acknowledgments

Surveys were planned and carried out under the MEXUS Pacifico program of intergovernmental cooperation. We thank D. N. Margetts for his help with camp logistics and F. Limon and J. Limon for providing facilities and support. Data acquisition software was written by J. Cubbage. The aircraft was chartered from Aspen Helicopter by the Southwest Fisheries Science Center. The pilot was J. Drust. This manuscript benefitted from the reviews of D. DeMaster, T. Gerrodette, B. Taylor, and two anonymous reviewers.

# Estimated drift gillnet selectivity for albacore *Thunnus alalunga*

**Norman Bartoo**
**David Holts**
La Jolla Laboratory, Southwest Fisheries Science Center
National Marine Fisheries Service, NOAA
P.O. Box 271, La Jolla, California 92038-0271

Drift gillnet (DGN) fisheries, some directed toward albacore *Thunnus alalunga* and some toward other species, have operated in the north and south Pacific Ocean. These fisheries, some of which had their beginnings decades ago, expanded in the early 1980s and exerted a substantial, but as yet unknown, mortality on Pacific albacore populations. Knowledge of the selectivity of DGNs is useful for applying complex population-dynamics techniques to the albacore population.

Several DGN experimental surveys conducted in the north and south Pacific Ocean have produced data on albacore distribution and gear selectivity. In 1984–85 the Southwest Fisheries Science Center of the National Marine Fisheries Service (NMFS) undertook an experiment to quantify DGN mesh-size selectivity for albacore. The experiment produced size-selectivity data for a single mesh size used in the U.S. DGN commercial fishery for albacore (184 mm; all mesh sizes referred to are stretch mesh measurements), in the eastern North Pacific Ocean. Other experiments designed to sample albacore were conducted by the Japan Marine Fishery Resource Center in 1980 (JAMARC 1983), 1982 (JAMARC 1985), and 1983 (JAMARC 1986). These experiments used other mesh sizes which produced complimentary data used in this study. The objective of this analysis was to quantify drift gillnet mesh-size selectivity for albacore, using existing data collected from various experiments and surveys in the Pacific Ocean.

## Methods

Various experiments providing data have been conducted independently at different times and in different areas (Fig. 1). Consequently, some assumptions had to be made concerning comparability of nets used and availability and vulnerability of fish sizes to be sampled. However, there was enough information to provide insights into net selectivity for albacore. The nets used in all the experiments were similar to typical Japanese commercial drift nets. All nets had similar mesh-hanging ratios, twine/mesh-size ratios, and were of multifilament construction (Table 1). These are the most important factors affecting the selectivity curve for a given mesh size (Hamley 1975).

Detailed descriptions for the JAMARC experiments, including set locations, timing, mesh size placement, etc, are contained in the JAMARC references. These experiments were designed to obtain information on resource distribution and catch rates for possible future commercial fisheries. In brief, the JAMARC North Pacific experiment was a 1yr survey beginning in the spring of 1980 (Fig. 1). It targeted albacore using nets with mesh sizes of 130–250mm. The JAMARC 1982 and 1983 experiments in the South Pacific were conducted in the area shown in Fig. 1 and targeted all tuna-like species, using 180 mm mesh nets in 1982, and 118 mm and 160–180 mm mesh nets in 1983.

The NMFS experiment targeted albacore. A total of 27 night sets was made: 12 sets in waters south of Point Conception and within 300 mi of shore; 7 sets in the vicinity of the Guide Seamount south of the Farallon Islands; and 8 sets approximately 1000 mi west of Oregon near 142°W long. and 45°N lat. (Fig. 1). All sets used 184 mm mesh nets.

In all the experiments using mesh sizes of >130 mm, the amount of gear fished during each set ranged from 2760 m to 10,800 m, and the number of sets ranged from 11 to 176 (Table 1). Nets in each experiment were deployed and retrieved as in typical commercial operations. Nets were deployed at dusk, and retrieval began at first light often extending into midmorning. Soak times were ~10–16 h/set.

## Data collected

Data published by JAMARC are limited to fork length (FL) frequencies by mesh size by set. The NMFS data include fork length-frequencies, maximum or largest body girth, and opercular girths for each fish, and notation on the mode of capture for each fish (tangled, wedged, or gilled). Fish were described as wedged or gilled when inserted into a mesh so that the entire perimeter of the mesh held the fish. This occurred at locations on the body from the snout to the point of maximum body girth. Fish were described as tangled when snared or tangled by fins or tail. Length-frequencies for U.S. troll-caught fish from the same time and areas are available for

comparison. Sample sizes of albacore caught by mesh size for each experiment, as well as the quantity of gear fished, are shown in Table 1.

## Results

### JAMARC 1980 data

Gear selectivity can only be estimated because there is no information on the actual size structure of the North Pacific albacore population (Hamley 1975). Data from several mesh sizes fished simultaneously and assumptions about shape, variance, and efficiency of the selectivity curves are required. The JAMARC 1980 experiment provided the only published dataset containing this information. Length-frequencies obtained in the 1980 experiment for mesh sizes 130, 150, 160, 170, 180, and 200 mm are shown in Fig. 2 (A–F). In all these mesh sizes, albacore captured had size modes at 53, 62, and 78 cmFL.

Two options are available for calculating an indirect selectivity curve: (1) Fitting a predetermined distribution function to data, using a method similar to that of Ishida (1962); or (2) estimating the selectivity of different meshes to one common size-class (mode) of fish and extrapolating to other mesh sizes (Regier & Robson 1966). Lack of an objective mathematical function in determining the shape of the selectivity curve in the first method, and the need for fitting the selectivity curve "by eye," required that a combination approach was employed.

A basic assumption of gillnet selectivity analysis is that selectivity is the same for those combinations of length interval L(i) and mesh size M(j) where the ratios of L(i)/M(j) are equal (Regier

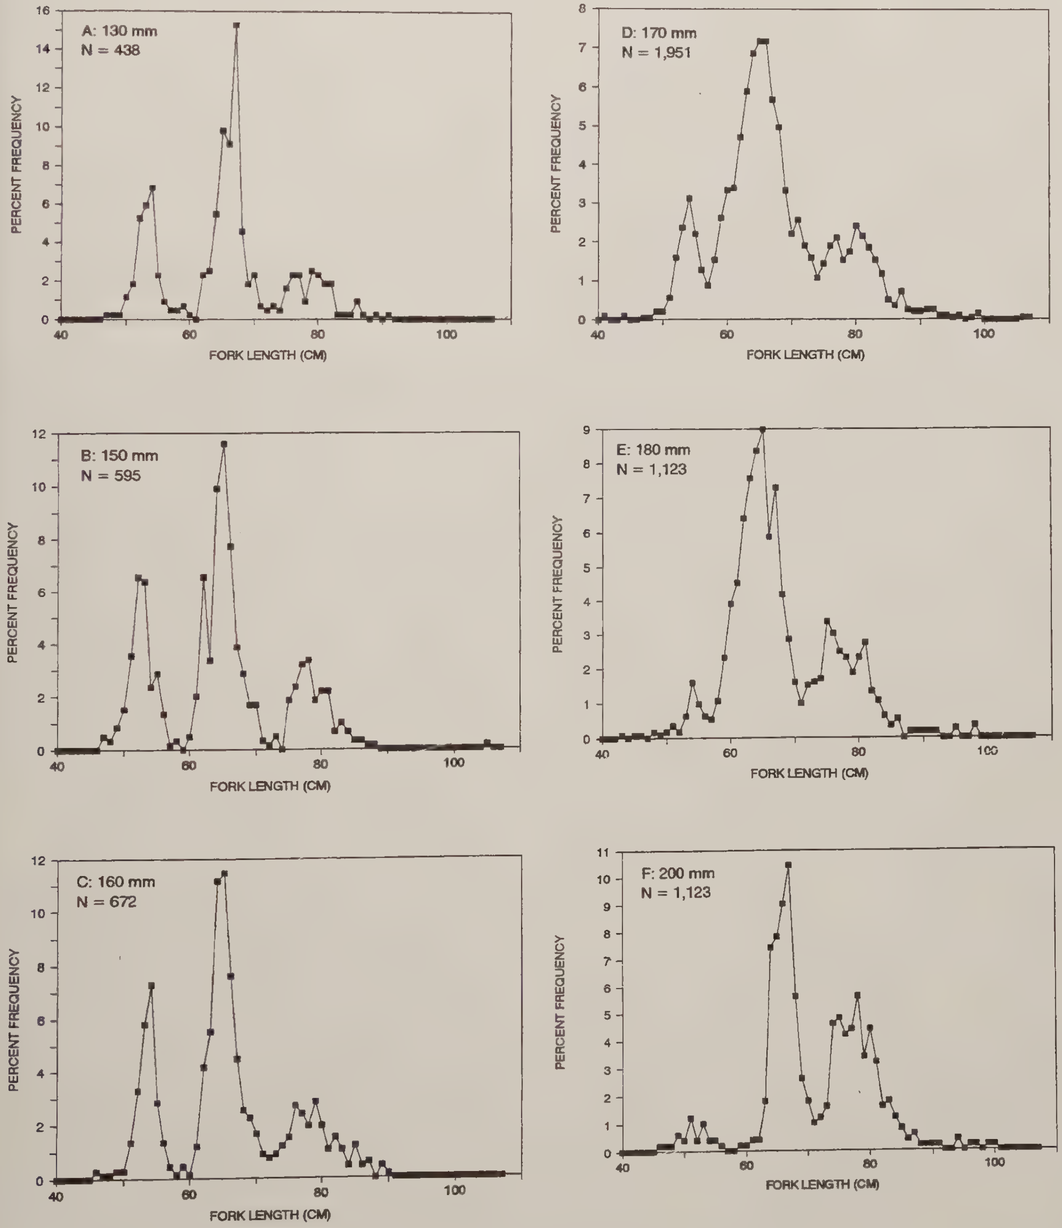

**Figure 2**

Percent frequency-of-occurrence of albacore *Thunnus alalunga* by fork-length interval by stretch-mesh size. Data from the 1980 JAMARC survey (JAMARC 1983). **(A)** 130mm mesh; **(B)** 150mm mesh; **(C)** 160mm mesh; **(D)** 170mm mesh; **(E)** 180mm mesh; **(F)** 200mm mesh.

& Robson 1966). This assumes that the length:girth ratio is the same for all fish. Each fork-length interval was divided by the appropriate mesh size of capture, and then multiplied by the appropriate observed frequency. This produced "generic" size-frequencies by mesh size. Each resulting size-frequency interval, by mesh size, was normalized to the greatest frequency. The resulting frequencies, one for each mesh size, were then scaled to an assumed 100% efficiency at the peak frequency sampled (the mid-60 cm mode); thus, differential sample sizes by mesh are taken into account. If all mesh sizes have the same selectivity curve, and no sampling variance, they would all be the same.

Rather than using the method of Ishida to describe a common selectivity curve (Regier & Robson 1966), the "mean" shape of the selectivity curve was estimated from the selectivity of the different mesh sizes for the largest (78 cmFL) and smallest (53 cmFL) modes captured by all mesh sizes. The curve obtained for the 53 cm mode described the left or ascending limb of the selectivity curve, and the curve for the 78 cm mode described the right or descending limb. Lengths between these two limbs were assumed to be sampled at 100%. This included some lengths with very low percent-frequencies (i.e., we assumed few fish were available) as well as the size mode near 62 cm. There was no assumption that the left and right limbs have the same shape.

For the 78 cm mode, the cumulative percent-frequency of capture vs. length of fish caught for all mesh sizes are shown in Fig. 3. When plotted on normal probability scales, cumulative percent-frequencies formed straight lines with virtually the same slopes. An average cumulative percent-frequency (subtracted from 100) provided the shape of the right limb (Fig. 4). This introduced the assumption of a constant variance and normal distribution (Hamley 1975). The same procedure provided the left limb of the selectivity curve which increased more rapidly or had a greater slope (Fig. 5).

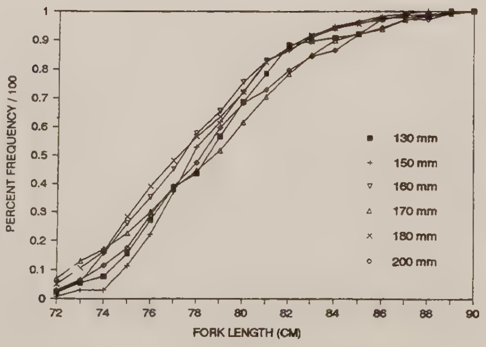

**Figure 3**
Cumulative percent frequency-of-occurrence by fork-length interval for 130 mm, 150 mm, 160 mm, 170 mm, 180 mm, and 200 mm stretch mesh sizes for the 78 cmFL mode of albacore *Thunnus alalunga* sampled in the 1980 JAMARC survey (JAMARC 1983).

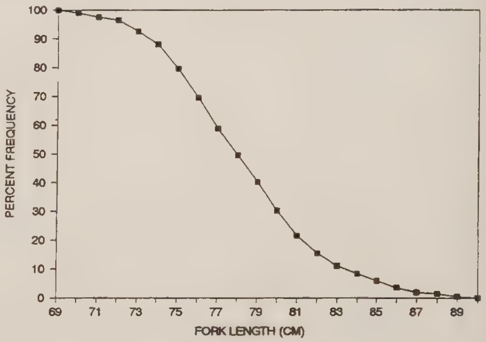

**Figure 4**
Mean selectivity-curve right limb for albacore *Thunnus alalunga* from the 78 cmFL mode sampled in the 1980 JAMARC survey (JAMARC 1983).

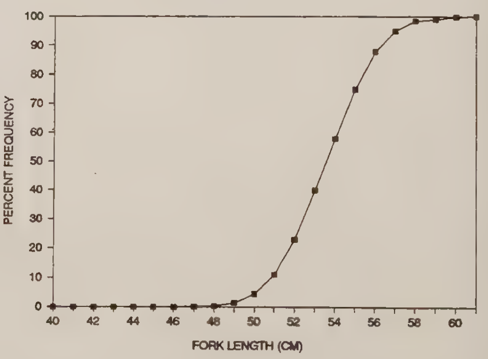

**Figure 5**
Mean selectivity-curve left limb for albacore *Thunnus alalunga* from the 53 cmFL mode sampled in the 1980 JAMARC survey (JAMARC 1983).

These two limbs must now be placed appropriately on the X axis for each mesh size. This is accomplished separately for each limb by mesh size. The sampling efficiency at 53.5 cmFL for each mesh size was estimated by linear regression. The observed maximum percent efficiency of sampling at the 53 cmFL peak was regressed against mesh size for all mesh sizes (Fig. 6). The estimated percent sampling efficiency at 53 cmFL for each mesh size is shown in Table 2. Using the same method, the percent sampling efficiency was estimated for 78 cmFL for each mesh size (Fig. 6, Table 2).

The family of selectivity curves by mesh size is shown in Fig. 7. These were determined by shifting the mean selectivity-curve limbs to the left or right so that sampling efficiencies at 53 and 78 cmFL matched the values in Table 2 for each mesh size. Fork lengths between the two limbs were assumed to be sampled with maximum efficiency, consistent with theory associated with unimodal selectivity curves (Hamley 1975).

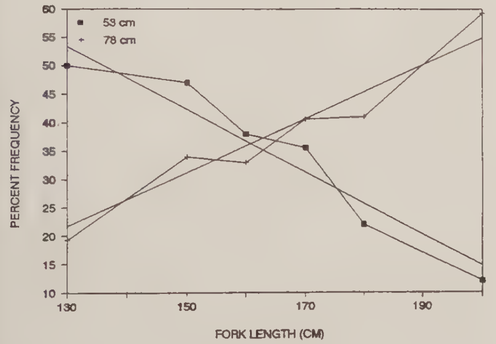

**Figure 6**

Linear regressions of observed maximum percent sampling efficiency at 53 cm and 78 cmFL against stretch-mesh size for albacore Thunnus alalunga.

**Table 2**

Estimated percent sampling efficiency for albacore *Thunnus alalunga* at fork lengths of 53 cm and 78 cm for various stretch mesh sizes.

| Mesh size (mm) | Fork length 53cm | (% efficiency) 78cm |
|---|---|---|
| 130 | 53.3 | 21.7 |
| 150 | 42.3 | 31.2 |
| 160 | 36.8 | 35.9 |
| 170 | 31.3 | 40.7 |
| 180 | 25.7 | 45.4 |
| 184 | 23.5 | 47.3 |
| 200 | 14.7 | 54.8 |

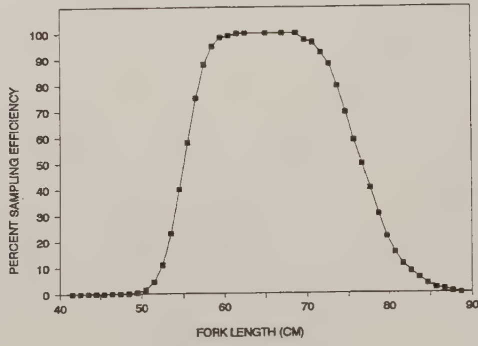

**Figure 9**

Selectivity curve for albacore *Thunnus alalunga* for 184 mm stretch-mesh size.

### NMFS 1985 experiment

Length-frequency data for albacore collected in the 184 mm mesh during the 1985 NMFS experiment are shown in Fig. 8. The estimated selectivity curve is shown in Fig. 9 and, as expected, is almost identical to the 180 mm mesh selectivity curve (Fig. 7). For comparison, length-frequencies from the NMFS experiment taken by both trolling jigs and drift netting in the same area are shown in Fig. 8. As predicted by the selectivity curve (Fig. 9), few fish <50 cm length were sampled by the 184 mm mesh even though the fish were assumed available to the net, as indicated by the size-frequency sampled by the trolling gear fished in the same area and time.

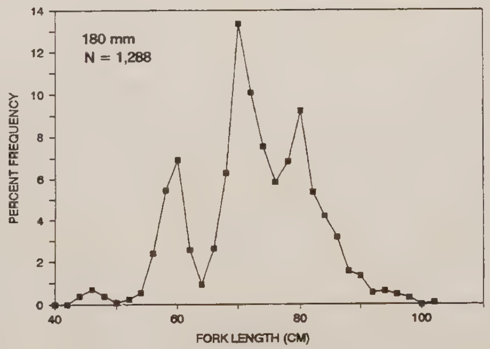

**Figure 10**
Percent frequency-of-occurrence by fork-length interval for albacore *Thunnus alalunga* for 180mm stretch mesh sampled by the 1982 JAMARC survey (JAMARC 1985).

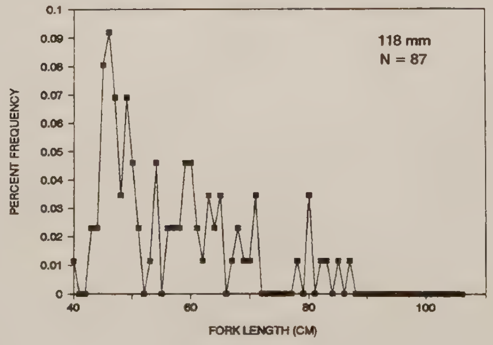

**Figure 11**
Percent frequency-of-occurrence by fork-length interval for albacore *Thunnus alalunga* for 118mm stretch mesh sampled by the 1983 JAMARC survey (JAMARC 1986).

### JAMARC 1982 experiment

The 1982 JAMARC South Pacific experiment collected data for a 180 mm mesh size. Length-frequency data obtained are shown in Fig. 10. The estimated selectivity curve for this mesh is the same as shown for the 180 mm mesh in Fig. 7. From inspection of the length-frequencies for 180 mm and 184 mm mesh sizes from the North Pacific, it was apparent that the South Pacific experiment sampled an albacore population with a different size structure. The results show a much greater proportion of fish in the 70–80 cmFL range than in the North Pacific sampling. This is also seen in samples taken from the U.S. troll fishery that operated in the South Pacific (Rensink 1991)

### JAMARC 1983 experiment

Length-frequency data obtained from the 1983 JAMARC South Pacific experiment using 118 mm mesh are shown in Fig. 11. The selectivity relationships developed from the North Pacific data do not accurately predict the expected selectivity curve for the 118 mm mesh. This is a result of small sample sizes and an observed peak size mode well below the sizes of albacore captured in the mesh sizes used to derive the selectivity curves.

## Discussion

Selectivity curves derived from the JAMARC 1980 experimental data appear similar in shape to selectivity curves presented for salmon *Onchorynchus nerka* and *O. keta*, slender tuna *Allothunnus fallai*, and mackerel *Scomberomorus niphonius*, and other fusiform fishes (Taguchi 1961, Ishida 1964, Shimazaki et al. 1984). The asymmetry of each selectivity curve (i.e., steeper on the left limb and flatter on the right limb) is similar to that observed for selectivity curves of other fusiform fishes (Hamley 1975) and is explained by the mechanics of capture. The smallest fish, retained by the net at some particular girth/mesh-perimeter ratio, tend to be caught near maximum girth. Also, the range of sizes providing the ratio is relatively narrow. For larger fish, the same ratio can be found over a larger range of fish sizes because the point of capture may be anywhere from the maximum girth forward to the snout tip. For example, maximum girth of albacore increases more rapidly than opercular girth as a function of length (Fig. 12) which extends or skews the

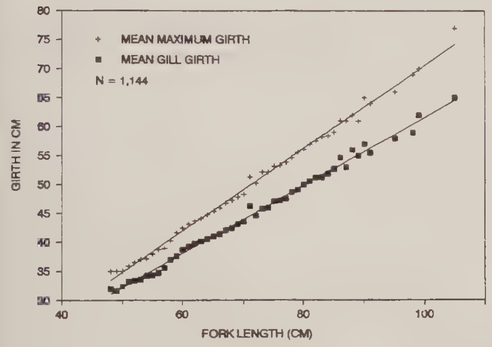

**Figure 12**
Relationship of albacore *Thunnus alalunga* maximum and opercular girths to fork length for 1144 fish sampled by the 1985 NMFS experiment.

right limb of the selectivity curve. This skewing can be troublesome when symmetrical or pre-determined selectivity curves are fit to data. The method used in this study minimizes this problem.

Assumptions that selectivity curves estimated from the 1980 JAMARC experiment applied to similar nets, such as the NMFS 184 mm mesh and the JAMARC-1982 180 mm mesh, appear acceptable from the data available. The principal factor limiting the application of these selectivity curves to other albacore populations is the girth/length relationships discussed above (Fig. 12). Significant changes in this relationship will change the steepness of the selectivity-curve limbs and the skewness.

Extrapolation of the mean selectivity curve to smaller mesh sizes than those providing the initial data may be improper based on the data observed for the 118 mm mesh. Although the sample size was relatively small, the apparent increase in tangling of larger fish caught in smaller mesh sizes compared with larger mesh sizes suggests that the right portion of selectivity curves for meshes <130 mm are more skewed. Tangled fish did not appear to be a problem in the NMFS or JAMARC 1980 datasets, presumably because all mesh sizes either gilled or wedged fish in the largest mode. Additionally, there may have been fewer larger fish available in the survey areas, as shown by troll-caught samples.

The absence of larger, tangled fish in both net-caught and troll-caught samples could result from reduced availability or vulnerability of larger fish in the areas sampled. Surface fisheries (i.e., drift net, troll, and pole-and-line) for albacore in the North Pacific produce catches with similar length-frequencies in the same areas (Bartoo & Foreman In press). However, albacore taken by subsurface longline gear at the same time and area are generally larger in length than those taken in the surface fisheries. This indicates albacore show differential availability or vulnerability between surface and subsurface gears. This could be due to spatial separation or behavior which may change with fish size. The results presented here assume that vulnerability to DGNs is relatively static over time.

## Acknowledgments

We acknowledge contributions to this work by several individuals. Thanks to Tony West and the crew of the F/V Steelfin II for their assistance during the cruises. Thanks to Earl Weber for helping conduct the NMFS drift gillnet experiment, Sonee Sonu for providing Japanese-English translations, and to the many reviewers for constructive comments on the manuscript. Finally, thanks to Karen Handschuh for production of the manuscript.

## I. ABSTRACT

During the 1990 North American albacore troll fishery, observers aboard United States troll vessels examined 19,526 albacore for evidence of driftnet damage. Results indicate that 13.4% of the albacore caught encountered driftnets. Proportions varied by area fished.

## II. INTRODUCTION

The Southwest Fisheries Science Center (SWFSC) in cooperation with members of the Western Fishboat Owners Association (WFOA) placed fisheries observers on U.S. trollers fishing in the North Pacific in 1990. This was part of a comprehensive impact assessment program on the effects of the high seas driftnet fisheries on the North Pacific albacore (*Thunnus alalunga*) stocks and other fisheries. Albacore which escape driftnets bear some external marks that provide direct evidence of interaction. Throughout this report, we refer to these external marks from driftnet encounters as damage. Damage may be minor or severe, and may include marks on the skin, bruising, and cuts and broken skin (loss of scales), missing areas of skin, and scars from any of the foregoing. This report describes the results of the 1990 observer project.

### 1. Background

Catches and catch-per-effort from the U.S. albacore troll and pole-and-line fisheries in the North Pacific have declined since the mid-1970's (Coan *et al.* 1991; Kleiber and Perrin In Press). In addition to the U.S. fishery, Japan and Taiwan each have a surface fleet and a longline fleet catching albacore in the North Pacific. Three high seas driftnet fleets also catch albacore in the North Pacific (Anon. 1989).

The small mesh (90 - 120 mm stretched mesh) driftnet fleets are made up of vessels from Japan, Taiwan and the Republic of Korea (ROK). The Japanese and Taiwanese fleets fish for flying squid (*Ommastrephes bartrami*) in the North Pacific Transition Zone from about May through December. The ROK fleet operates there the entire year. The incidental catches of albacore by these driftnet fisheries are not precisely known.

The large mesh (160 - 180 mm stretched mesh, Bartoo and Holts 1991) driftnet fleet is made up of vessels from Japan and Taiwan. Albacore is a major component of that catch. Taiwan has a developing large mesh fishery for albacore. The impact of these fleets on albacore is largely unknown. Taiwan and Japan have imposed internal regulations on their driftnet fleets to limit fishing effort in the higher latitudes and minimize interceptions of high seas salmon.

Although driftnet catches and landings for North Pacific albacore are incomplete and unreported for some fleets, the aggregate reported annual landings for driftnet fisheries exceeded 20,000 mt in 1988 (Tsuji *et al.* 1992). In the mid-1980's U.S. albacore fishermen began reporting increasing numbers of albacore injured or scarred by encounters with high seas driftnets. Concerns focused on the impact of driftnet fisheries on the North Pacific albacore stock and the direct interaction with the U.S. albacore troll fleet.

## 2. Troll Observer Project

In 1990, SWFSC biotechnicians observed 6 complete fishing trips aboard 5 different troll vessels. Vessels were selected to provide data over the entire season and cover the entire fishing area. The cruise tracks of the observed vessels are shown with the entire catch distribution of the troll fleet in Figure 1. The fishery followed eastward migrating albacore beginning north of Hawaii in June, moved eastward to 135°W in July, and remained east of 135°W in August and September (Coan *et al.* 1991). Operations and observations covered a wide area of the North Pacific Ocean. The project goals were to document and estimate the interaction between high seas driftnet and North American troll fisheries, and to provide biological information from which delayed mortality of albacore due to net encounters might be inferred. Specific objectives are as follows:

A. Describe the type and severity of driftnet damage on troll-caught albacore.
B. Estimate the relative frequency of undamaged albacore and damaged albacore.
C. Estimate the size-frequency of undamaged albacore and damaged albacore.
D. Determine the relative physiological condition of troll-caught albacore that show gillnet damage.

Here, we report results relating to the first 3 objectives.

## III. METHODS

Driftnet marks are most visible when the fish is boated. Most marks disappear or are rendered indistinguishible once the fish is frozen or dies on deck. Observers examined each fish landed and noted net scars or marks using a set of reference photographs detailing the type and severity of injuries (Figure 2). These were coded as:

| Code | Damage Description |
|---|---|
| 0 | No gill net damage to fish. |
| 1 | Minor damage along side(s) of fish, pattern of stripes due to minor scale loss where fish forces its way through or along the net. |
| 2 | Minor damage to head, chiefly forwards of pectoral fins, brush-like pattern of scale loss. |
| 3 | Severe damage with bruising or scraping away of parts of the skin, primarily in area of greatest girth and mostly on dorsal surface. |
| 4 | Old gill net damage of any degree that is partially or completely healed. These are assumed to have occurred previously. |

Observers photographed, for later analysis, fish which showed damage but could not be classified on board.

In addition to damage code, observers collected information on fork lengths, maximum girth, and weights for as many fish as possible. Fishing operations usually continued all day from first light to just after dark.

## IV. RESULTS

Six cruises, totalling 377 observed sea-days were completed between the end of May and the end of October 1990. A total of 25,177 albacore were caught and boated during the cruises. Seventy-eight percent of these (19,526) were examined for driftnet related injuries and measured for fork length and maximum girth. A total of 8,720 fish were weighed to the nearest pound (transformed to kg). Catch-per-fishing-day averaged 66.8 fish-per-day but varied considerably between cruises (Table 1). One vessel (Cruise 5) was on a charter with WFOA as a scout boat and did not fish routinely.

Albacore of three distinct size modes were caught throughout the North Pacific apparently representing 2, 3, and 4 year old fish (Bartoo and Foreman In Press; Fig. 3). Length modes were at 54, 65 and 80 cm corresponding to weights of 3.5, 5.7, and 10.6 kg.

Overall, 86.6% of the observed catch showed no evidence of net related damage (Table 2). Recently damaged albacore (damage codes 1,2 & 3) totalled 9.2%, while an additional 4.2% had healed scars, possibly from net encounters during the previous fishing season (code 4). Within the recently damaged albacore, 3.5% had minor damage; 5.2% had moderate injuries on the head, gill covers and fins; while 0.5% had severe bruising with significant loss of scales with skin damage to their head, sides and fins.

Observers measured fork lengths (FL) of 11,868 albacore east of 140°W in July, August and September and 7,658 albacore west of 140°W in June and July. The catch taken west of 140°W had larger fish than the catch east of 140°W (Fig. 4). These large fish averaged 9 - 11 kg (20 to 25 lbs). Although the sample size was small, injuries from recent encounters with driftnets were observed on nearly 18% of the catch.

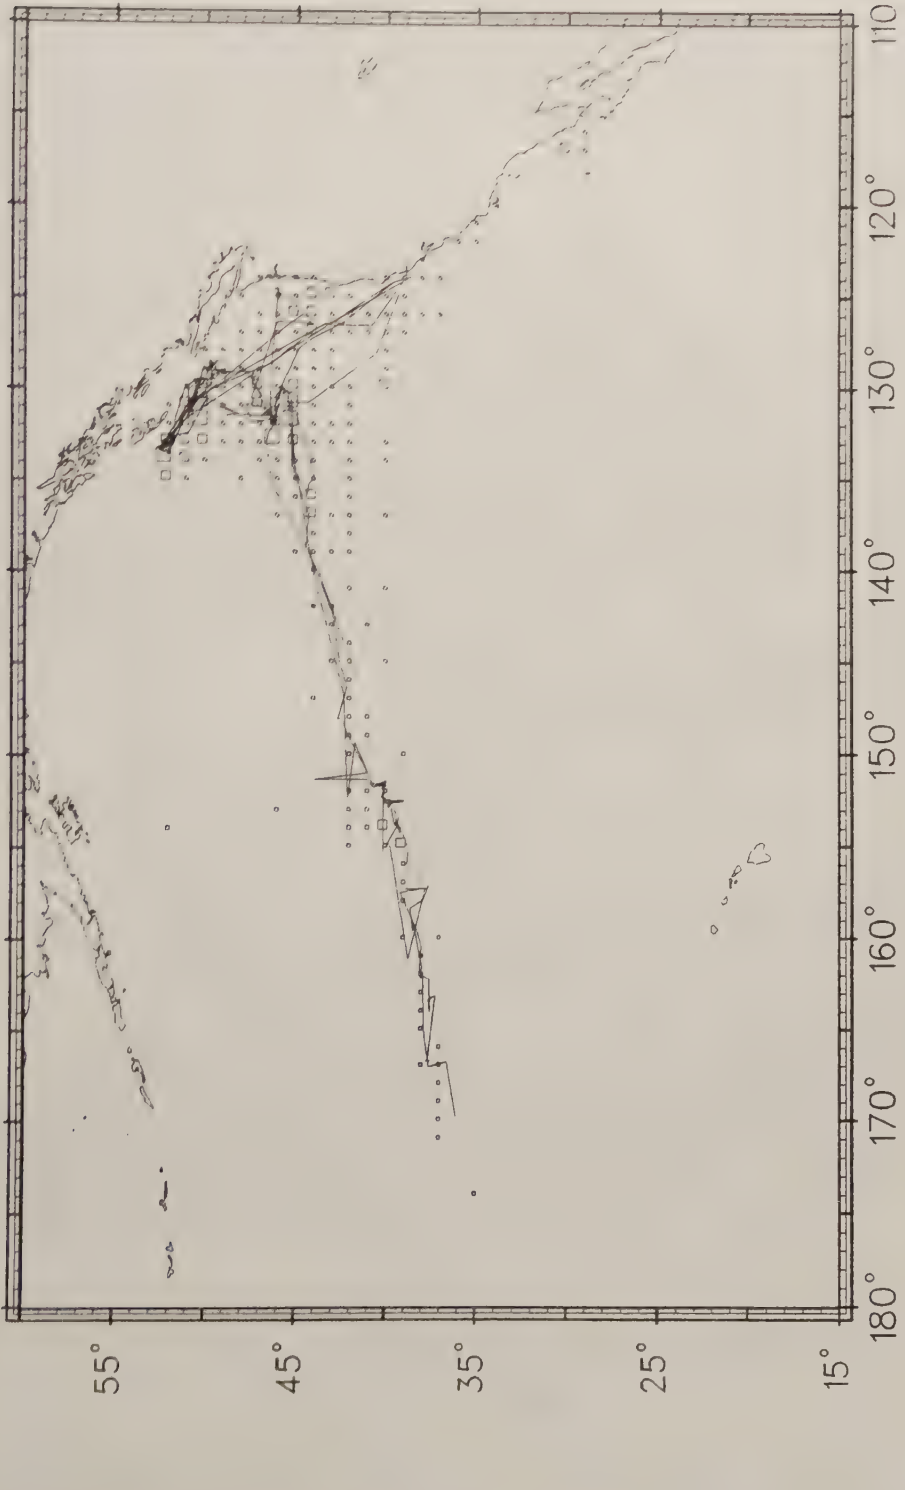

Figure 1. Cruise tracks for the observed albacore troll vessels and the distribution of the 1990 U.S. troll catch (squares). (small squares are catches of 1-1000 fish, medium = 1001-10000 fish, large = +10000 fish). Three vessels departed Honolulu and three departed from the mainland. All cruises terminated on the west coast of United States.

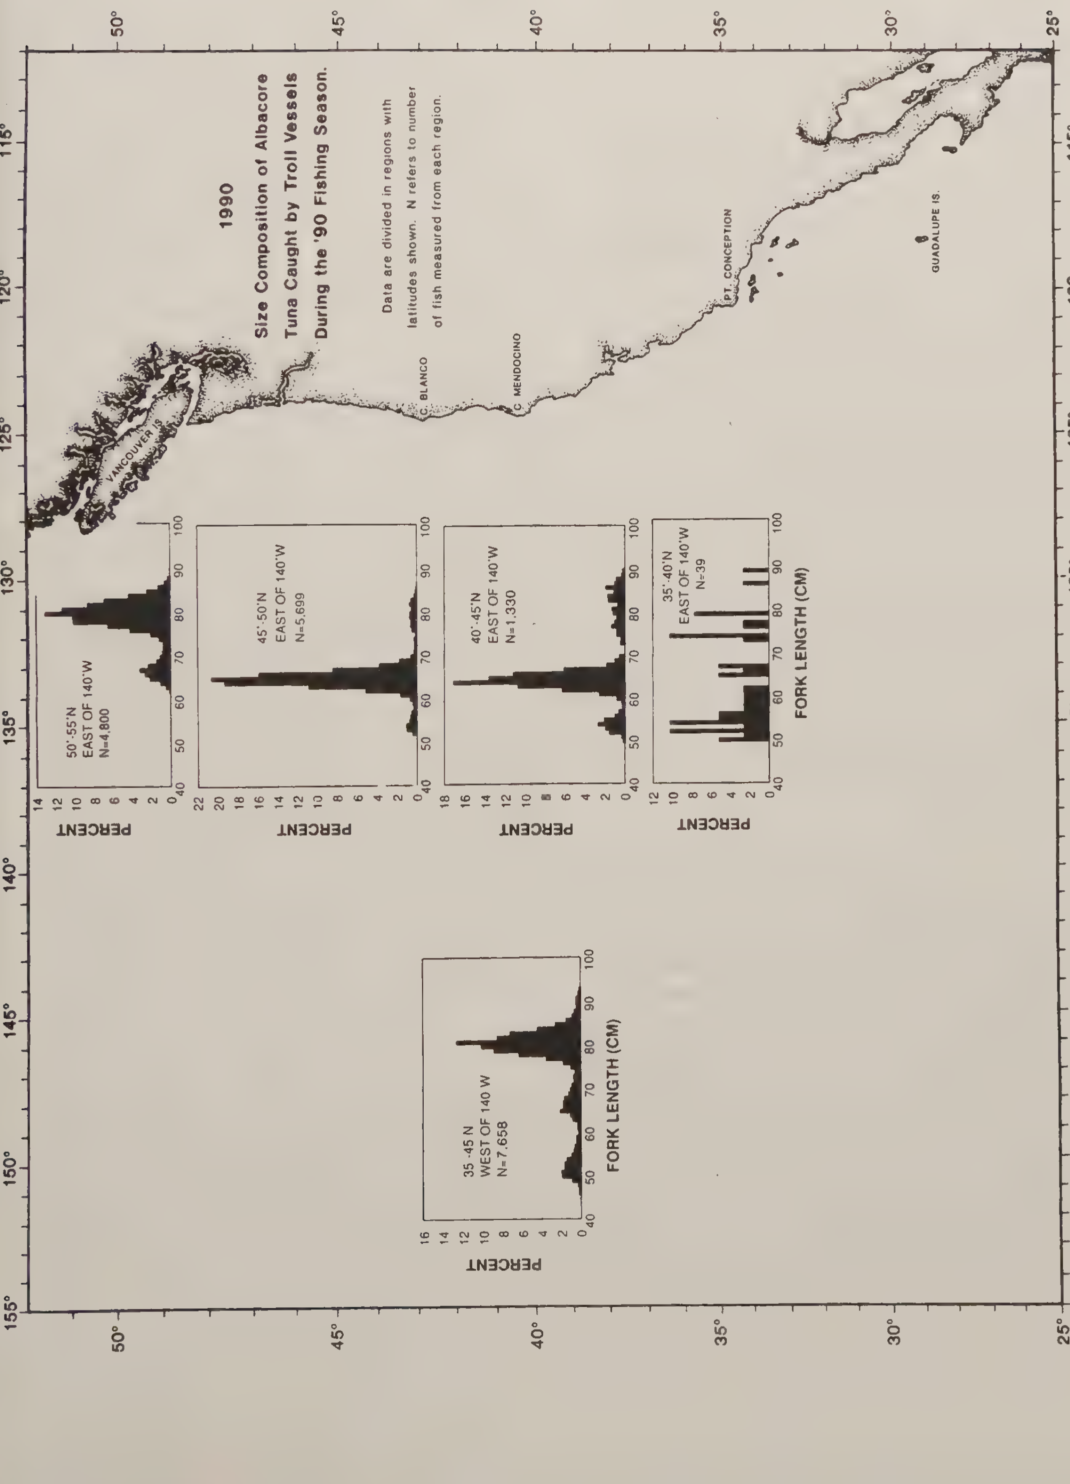

Figure 4. Albacore length frequencies by fishing areas of the North Pacific.

Old and healed scars, from a previous time, appeared on less than one percent of the catch west of 160°W but increased to about 5% east of 160°W (Table 2).

By the end of July, all observed vessels were fishing east of 140°W and south of 50°N, catching fish weighing 5 - 9 kg (12 to 20 lbs). These fish were caught throughout the month of August and early September. The incidence of fresh injuries remained at about 6.7% in the coastal areas and the incidence of old injuries remained fairly constant at about 5 percent.

Albacore taken north of 50°N had a higher proportion of large (80 cm FL) fish than those caught east of 140°W and south of 50°N (Figure 4). No fish less than 63 cm FL were sampled north of 50°N. Fishing remained moderately good north of 50°N until seasonal storms out of the Gulf of Alaska forced many fishing vessels to return home by the end of September. Few recently damaged fish were observed north of 50°N although the proportion of old and healed damage changed little from that seen just off Washington and Oregon (5.5% to 4.9% respectively).

The observed length frequencies varied considerably in different fishing locations. Length frequencies of injured fish did not vary greatly from uninjured fish within each area examined. The length frequencies, by area, for undamaged (code 0), recently damaged (codes 1-3) and old damage (code 4) are shown in Figures 5, 6 and 7 respectively. No previous damage estimates are available from the 1989 season that could help describe survival of fish sampled (code 4) in the 1990 fishing season.

The length-weight relationship for all 8,720 weighed albacore is shown in Figure 8.

## V. DISCUSSION

Our results show that 13.4% of the albacore caught encountered driftnets. These proportions are less than some reports from fishermen which ranged from 40% to 90% of the catch. Our data do indicate considerable variation in damage on a daily basis, ranging from none to 100% of the catch. Our results are consistent with those reported for albacore in the south Pacific which ranged from 4.5% to 14.5% of the catch in 1989 and 1990 (Hampton *et al.* 1991).

Our results show that 9.2% of the 1990 catch evidenced new damage and that higher proportions were found to the west. The apparent "gradient" in proportion of net marked fish from west to east may be explained by the migration pattern of albacore and the timing and location of the driftnet and troll fisheries. Additionally increased short-term mortality of a few days or weeks due to net damage may contribute.

Based on tag information the migration pattern of juvenile North Pacific albacore of the size caught by the driftnet and troll fisheries is predominately east-west (Otsu and Uchida 1963, Clemens 1961). The fish move from waters off Japan in the spring across the Pacific in the Subarctic Transition Zone (STZ) and enter the coastal waters of North America in July. In late September albacore leave the east Pacific and return to waters off Japan. This annual pattern may be repeated until age 5 or 6. Although some portion of the population makes the complete trip across the Pacific in just a few months it is apparent that a considerable proportion of the population is not available at the extreme ends of the population distribution (Bartoo and Foreman in press).

The troll fishery as shown in Figure 1 begins near the mid-Pacific in May or June and moves with the advancing albacore to the east. Both small and large mesh driftnet fisheries in 1990 were distributed as shown in Figure 9 with most of the effort centered between 170°E and 170°W and becoming less east of 170°W. Collectively these fisheries operate the year around with considerably higher effort east of 170°E after May.

Higher proportions of marked fish are seen west of 140°W where the driftnet and troll fisheries overlap in area and time. Lower proportions of marks are seen east of 140°W, outside the distribution of the driftnet fisheries. Additionally, some albacore may migrate into the troll fishery from areas south of the driftnet fishery distribution (Laurs and Lynn 1977) and dilute the marked portion of the population.

The proportions of marked fish in the east may also be decreased by an increase in mortality associated with encountering and escaping a driftnet (alive) which reduces the number of albacore available to be recaptured in the troll fishery. This would logically seem to increase directly with the severity of injury and passage of time (as the albacore move eastward).

## VI. ACKNOWLEDGEMENTS

We wish to thank the Western Fishboat Owners Association for their help in locating owners of fishing vessels for placement of our observers. We also want to thank the owners of those vessels for their support. We are truly indebted to the observers who examined and measured the nearly 20,000 albacore. Finally, thanks to the reviewers whose suggestions greatly improved this manuscript.

Bence, J.R., A. Gordoa, and J.E. Hightower. 1993. Influence of age-selective surveys on the reliability of stock synthesis assessments. Can. J. Fish. Aquat. Sci. 50: 827–840.

We used Monte Carlo simulations to examine the reliability of assessments following a method of separable catch-at-age analysis (Methot's stock synthesis approach). Our simulations were based on the widow rockfish (*Sebastes entomelas*) fishery off the west coast of the continental United States. We designed the study to examine how the performance of the method depended upon the age-specific selectivity pattern of a survey of relative abundance. When survey selectivity increased asymptotically with age, stock synthesis estimates of final year biomass (and most other parameters) tended to be closest to the correct value. When the survey concentrated on young fish the estimates were least reliable. When the survey selectivity was "dome-shaped," concentrating on intermediate-aged fish, estimates were somewhat less precise (and less accurate) than for the asymptotic pattern but much more precise than for the survey concentrating on young fish. Predictably, estimates of recruitment and biomass were better at a higher fishing mortality rate and when the magnitude of survey error was lower. Generally, mean errors in estimated biomass and recruitment were positive, while median errors were close to zero. This pattern is due to transformation bias associated with a lognormal error structure.

Nous avons utilisé des simulations de Monte-Carlo afin de déterminer la fiabilité d'évaluations réalisées par analyse à composantes séparables des prises selon l'âge (synthèse des stocks de Methot). Nos simulations étaient fondées sur la pêche de la veuve (*Sebastes entomelas*) réalisée au large de la côte ouest des États-Unis. Nous avons conçu l'étude de façon à déterminer dans quelle mesure le rendement de la méthode dépendait de l'allure de la sélectivité spécifique quant à l'âge d'un relevé de l'abondance relative. Lorsque la sélectivité du relevé augmentait de façon asymptotique avec l'âge, l'estimation par synthèse du stock de la biomasse de dernière année (et de la plupart des autres paramètres) tendait à se rapprocher le plus de la valeur réelle. L'estimation la moins fiable était obtenue lorsque le relevé portait surtout sur les poissons les plus jeunes. Lorsque la sélectivité du relevé correspondait à la forme "en dôme" et portait donc sur les poissons d'âges intermédiaires, l'estimation était quelque peu moins précise (et moins exacte) que celle du relevé d'allure asymptotique, mais demeurait plus précise que celle du relevé portant surtout sur les jeunes poissons. Comme on peut s'y attendre, l'estimation du recrutement et de la biomasse était meilleure lorsque le taux de mortalité par pêche était plus élevé et que l'erreur du relevé était plus faible. De façon générale, l'erreur moyenne de la biomasse et du recrutement estimé était positive tandis que l'erreur médiane se rapprochait de zéro. Ce phénomène s'explique par des erreurs de transformation liées à un biais de structure lognormale.

Separable age-structured population models are widely used to analyze fishery catch-at-age data in order to estimate recruitment, fishing mortality rates, and stock abundance. These models assume that the fishing mortality rate can be separated into a product of year and age effects (Doubleday 1976). In most instances, a wide range of solutions to a separable model can fit a set of fishery age-composition data about equally well (Doubleday 1976; Deriso et al. 1985; Shepherd and Nicholson 1986). Thus, for reasonably accurate estimates of abundance, separable models require auxiliary data such as information about abundance from trawl surveys or measures of fishing effort (Doubleday 1976; Deriso et al. 1985; Kimura 1990; Methot 1990).

In this paper, we examine the performance of a separable model when survey data on the relative abundance of a stock are available. Our objective is to compare the merits of surveys with different types of age-specific selectivity patterns. Surveys that cover the habitat occupied by adult fish sometimes have selectivity increasing to an asymptote (Rollefsen 1953). Other surveys that use selective gear (e.g., gill net or hook-and-line) or concentrate in a subhabitat occupied predominantly by certain ages may have either a dome-shaped selectivity with peak selectivity at an intermediate age (e.g., Hamley 1975; Methot and Hightower 1990; Ralston 1990) or peak selectivity on recruits (young fish) (Methot and Hightower 1990; Wyllie Echeverria et al. 1990). The separable model we use belongs to Methot's (1990) family of stock synthesis models, which are widely used in assessing fish stocks off the west coast of North America (PFMC 1990). We fit the model to simulated data based on the biology of widow rockfish (*Sebastes entomelas*), which supports a significant trawl fishery off the west coast of the continental United States. This species, like other *Sebastes*, is relatively long-lived, with a maximum reported age of 50 yr in California and an estimated natural mortality rate of 0.15. Although we used the biology of widow rockfish as a basis for our modeling, our goal was to determine general results regarding the performance of the stock synthesis model, not to mimic the widow rockfish fishery exactly.

## Simulation Design and Methodology

The basic stock synthesis approach is to invoke a dynamic model both of the fishery and of the process by which data are generated and then fit this model to the available data (Methot 1990). The synthesis model estimates a suite of parameters and uses these along with prespecified constants to calculate fitted data values. These fitted or "synthetic data" are then compared with the observed data in likelihood equations, and a search is done for the set of parameter estimates that maximizes the likelihood.

We examined the performance of the stock synthesis model by Monte Carlo simulation. We did 200 simulations for each of the 18 combinations of age-specific selectivity patterns for the survey, average fishing mortality rates during the simulations, and levels of survey error.

We considered surveys with (1) increasing asymptotic selectivity, (2) dome-shaped selectivity, and (3) maximum selectivity for young fish (recruits) (Fig. 1). For each survey selectivity pattern, we used two average levels of fishing mortality (low: mean fishing mortality rate at age 10 ($F$) = 0.075 (half the natural mortality rate, i.e., $M/2$ and high $F$ = 0.30 ($2M$)) and three levels of survey error: low (CV = 10%), medium (CV = 25%), and high (CV = 50%). Note that all cases started in an unfished condition, which is a reasonable portrayal of the widow rockfish fishery prior to 1980. The range of error in surveys is in accord with typical estimates of survey precision (e.g., Rivard 1981; Pope 1983; Pope and Gray 1983; Weinberg et al. 1984).

We first describe the synthesis model used in our simulations, then describe how we generated simulated data sets, and lastly turn to details on how the "best fit" of the synthesis model to the simulated data sets was achieved for each run. With only minor exceptions discussed below, the model fitted in the simulated assessments (i.e., the synthesis model) was the same as the model we used to produce the simulated data sets. That is, our evaluation of the stock assessment methodology did not include appreciable process error.

### Stock Synthesis Model

Following after Lenarz and Hightower's (1988) assessment of the widow rockfish fishery, nine age groups of fish were included in the synthesis model (age 5 through 13+), and we followed the population for a 15-yr time period. The numbers of fish of each age group, starting with age 6, present at the beginning of the first year ($N_{a,1}$, $a$ = 6, ..., 13) and the number of age 5 fish recruiting at the beginning of each year ($N_{5,y}$, $y$ = 1, ..., 15) were estimated as formal parameters as described below. Given estimates of initial numbers and recruitment, the numbers of age $a$ fish at the beginning of each year $y$ after the first ($N_{a,y}$, $a$ = 6, ..., 12; $y$ = 2, ..., 15) were simply the survivors from the previous year:

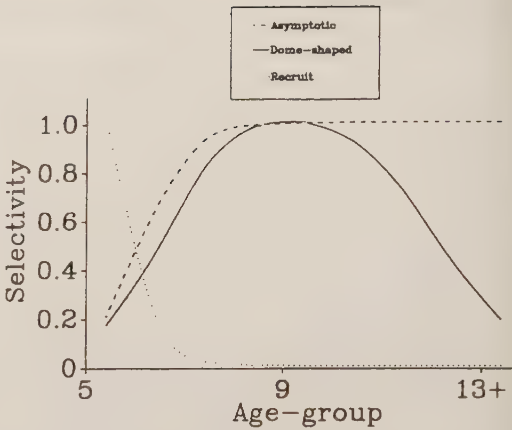

FIG. 1. Selectivity functions for the survey. Note that the dome-shaped function was also the fishery selectivity pattern. Parameters used to generate these functions are given in Table 1. Selectivity has been renormalized, for this presentation only, so that the maximum value is 1; this allows the selectivity patterns for the different surveys to be presented on the same scale.

$$(1)\quad N_{a,y} = N_{a-1,y-1}\exp(-\{M + F_{a-1,y-1}\})$$

where $M$ is the natural mortality rate and $F_{a,y}$ is the fishing mortality rate for age $a$ fish in year $y$. For the 13+ category, numbers in each year after the first ($N_{13,y}$) were given by

$$(2)\quad N_{13,y} = N_{12,y-1}\exp(-\{M + F_{12,y-1}\}) + N_{13,y-1}\exp(-\{M + F_{13,y-1}\})$$

which were simply the survivors of the 13+ category plus the surviving 12-yr-olds from the previous year. Thus, numbers-at-age, excluding the initial age composition and recruitment each year, were not estimated as parameters, but instead were calculated from the initial age composition ($N_{a,1}$, $a$ = 6, ..., 13), recruitments ($N_{5,y}$, $y$ = 1, ..., 15), age- and year-specific fishing mortality rates ($F_{a,y}$, $a$ = 5, ..., 13; $y$ = 1, ..., 15), and the natural mortality rate ($M$).

$F_{a,y}$ was modeled as being separable:

$$(3)\quad F_{a,y} = F_y\, s_{f,a}$$

where $s_{f,a}$ was the fishery ($f$) selectivity on age $a$ fish and $F_y$ scaled overall fishing mortality in year $y$. In the model, $s_{f,10}$ was set equal to 1, so that $F_y$ equals $F_{10,y}$, the fishing mortality rate on age 10 fish in year $y$. A restriction of this type is necessary to parameterize uniquely the age and year effects (Doubleday 1976). We chose to normalize to selectivity at a constant age, rather than to the age of estimated maximum selectivity, as is often done, so that $F_y$ would have a constant definition. Thus, selectivity for some ages could exceed unity.

Age-group-specific fishery selectivity was assumed to follow a double-logistic function (Table 1; Fig. 1). The double-logistic

TABLE 1. Parameters and values used by the stock synthesis model (SSM) and by the simulation model. Some of these values were estimated by the SSM as formal parameters (E), others were assumed known (K), and others were determined by assumed constraints (C) (see text). Note that "known" values used for the SSM were the same as the values used in the simulations.

| Parameter | Description | Treatment by SSM | Values used by simulation |
|---|---|---|---|
| $F_y$ | Fishing mortality multiplier for year | C | From lognormal distribution with CV = 30% and mean of 0.075 or $0.30 \cdot yr^{-1}$ |
| $N_{5.y}$ | Recruitment at age 5 in year $y$ | E | From lognormal distribution; mean = 17.8$M$, variance = 110.3$M$ |
| $N_{a.1}$ | Initial numbers-at-age | E | Based on distribution for recruitment parameters |
| $\alpha_{f.i}$, $\beta_{f.i}$, $\alpha_{f.d}$, $\beta_{f.d}$ | Fishery selectivity parameters | E | −9, 1.46, 13.28, −1.14 |
| $\alpha_{s.i}$, $\beta_{s.i}$, $\alpha_{s.d}$, $\beta_{s.d}$ | Survey selectivity parameters | E | |
| | Recruit | | −1, 0.1, 14, −2.655 |
| | Dome-shaped | | −9, 1.46, 13.28, −1.14 |
| | Asymptotic | | −11.39, 2, 13.28, −0.001 |
| $q$ | Survey proportionality constant | C | 1 |
| $M$ | Natural mortality rate | K | $0.15 \cdot yr^{-1}$ |
| $\sigma_s$ | SD of log survey catch | K | Produces CV = 10, 25, or 50% |
| $\sigma_c$ | SD of log fishery catch | K | Produces CV = 1% |

function is flexible and can be used to model a wide variety of selectivity patterns, including nearly knife-edged, dome-shaped, and asymptotic (Methot 1990). This function is composed of two logistic functions, one increasing and the other decreasing. The product of the two logistic functions, after rescaling, was selectivity:

$$(4)\quad s_{f.a} = \frac{[1/\{1+\exp(-(\beta_{fi}\, a + \alpha_{fi})\}]\,[1/\{1+\exp(-(\beta_{fd}\, a + \alpha_{fd})\}]}{\lambda_{10}}$$

where $\alpha_{fi}$, $\alpha_{fd}$, $\beta_{fi}$, and $\beta_{fd}$ are the parameters of the increasing ($i$) and decreasing ($d$) logistic functions and $\lambda_{10}$ is equal to the value of the numerator of the equation for $a$ (age) = 10. $\alpha_{fi}$, $\alpha_{fd}$, $\beta_{fi}$, and $\beta_{fd}$ were estimated as formal parameters, while the overall scalers of fishing mortality, $F_y$, $y = 1, ..., 15$, were determined by constraints as described below. (Note that the selectivity of the 13+ group was assumed equal to the value predicted by equation 4 for $a = 13$.)

The last determinant of population dynamics was the natural mortality rate ($M$), which was fixed at a value of 0.15 based on prior information (Hightower and Lenarz 1986).

We now turn to how the synthesis model calculated its synthetic data to compare with observed data. We assumed that the observed data for each 15-yr period consisted of fishery age-composition data, total biomass of fishery catch during each year, annual survey age composition data from subsamples of the survey catch, and catch per unit effort (CPUE), a relative annual index of biomass available to the survey gear.

The numbers of each age caught by the fishery during each year were assumed by the synthesis model to follow the Baranov catch equations:

$$(5)\quad \eta_{f.a.y} = N_{a.y}\, F_{a.y}\, [1\text{-}\exp\{-M + F_{a.y})\}]/[M + F_{a.y}].$$

The synthesis model treated the fishery catch data as consisting of two independent pieces of information: (1) the proportion of the total numbers caught each year that fell into each age-group (i.e., the age-composition data), which were directly calculated from the $\eta_{f.a.y}$'s, and (2) the total biomass caught ($C_{f.y}$). Catch biomass was calculated simply as the sum over ages of the product of numbers caught at each age (from equation 5) and the weight at each age. The weight-at-age relationship was assumed to be known a priori, and equations developed by Lenarz (1987) and Phillips (1964) for widow rockfish were used to define this relationship.

Like the fishery catch data, the survey data were treated as containing two independent types of information for each year: (1) the proportions caught by the survey at each age (the age-composition data) and (2) a CPUE value representing an index of biomass available to the survey gear. The survey was assumed to have an insignificant effect on the stock size and to have occurred after recruitment for a given year, but before fishing or natural mortality. The synthesis model calculated the proportions-at-age caught by the survey in year $y$, the $P_{s.a.y}$'s, as proportional to the product of the model's current values for abundance of each age and the selectivity of the survey for the corresponding age ($s_{s.a}$):

$$(6)\quad P_{s.a.y} = s_{s.a} N_{a.y} / \Sigma_i\, s_{s.i} N_{i.y}\,.$$

In our application of the synthesis model, the survey selectivity pattern was defined by a double logistic function of age, just as the selectivity of the fishery was. The four parameters defining the function were estimated as formal parameters (Table 1). The CPUE index was fit by the synthesis model by assuming it to be proportional to the weighted (by selectivity) sum over ages of population weights-at-age. Population weight-at-age was simply the product of abundance-at-age $N_{a.y}$ and expected weight-at-age of an individual ($w_a$, assumed known as described above). Thus, the survey CPUE index in year $y$ was

$$(7)\quad C_{s.y} = q\Sigma_a\, w_a\, s_{s.a}\, N_{a.y}\,.$$

The proportionality constant $q$ was determined by a constraint as described below.

### Generation of Simulated Data

For each run, a new simulated data set was generated. All parameters defining the simulation model are given in Table 1, along with their values or the distribution from which they were generated.

The simulation model made essentially the same assumptions as were incorporated into the stock synthesis model described above. Given the initial age composition, recruitments, fishing mortality rates, and other (fixed) parameters (Table 1), we used equations 1–5 to simulate population dynamics and fishery catch over time. $M$ was fixed at 0.15, and the same set of fishery selectivity parameters (Table 1) was used in all cases, leading to a dome-shaped selectivity function (Fig. 1).

Each simulation run used randomly generated recruitments ($N_{5,y}$, $y = 1, \ldots, 15$), initial numbers at age ($N_{a,1}$, $a = 6, \ldots, 13$), and fishing mortalities ($F_y$, $y = 1, \ldots, 15$) in each year. Recruitment was generated from a lognormal distribution with specified mean and variance (Table 1, estimated from Hightower and Lenarz 1989). Initial numbers-at-age were calculated from randomly generated recruitment values, reduced for the cumulative natural mortality up to the age in question. As indicated above, this assumes insignificant fishing prior to the first year of the simulation. For age 13+, initial numbers were generated and summed for the youngest 50 year-classes in this age-group (numbers at older ages were negligible). Fishing mortality rate on age 10 fish ($F_y$), with the mean appropriate for the given set of runs, was generated from a lognormal distribution. The CV for $F_y$ was 30%, roughly approximating the variability in estimated fishing mortality seen in a number of different assessments of rockfish stocks (PFMC 1990). Note that the expected fishing mortality rate was constant over years and was not changed in response to the current estimate of the status of the stock.

In this model the expected level of recruitment was not a function of the biomass of the stock when the year-class was generated, and this implies that substantial compensation was taking place. The assumption was useful because direct effects of fishing on adult stock composition were not confounded with indirect effects on recruitment that would cause the average magnitude of recruitment to differ between low and high fishing mortality rates.

Both the fishery and survey age-composition data for each year were generated as multinomial samples with effective sizes of 400. The expected proportions-at-age were calculated directly from catch-at-age (equation 5) or by equation 6 (the survey). Some estimates of the variance of catch-at-age numbers for west coast groundfish suggest that our admittedly somewhat arbitrary choice of effective sample size (after Fournier and Archibald 1982) may not be unrealistic (Sen 1986; Methot 1990; Parker and MacCall, unpublished manuscript[2]). The total biomass caught by the fishery was assumed to be measured precisely, so observed catches were generated from a lognormal distribution with a CV of 1% about the true value, matching the error assumed by the assessment methodology in likelihood calculations (see below). The survey index of biomass was generated from a lognormal distribution with CV's of either 10, 25 or 50%, depending upon the particular run, and an expected value specific to the given year of the run. The expected index value was the sum of the products of expected survey catch-at-age and weight-at-age. The expected survey catch-at-age is given by numerator of equation 6, multiplied by $q$ (which was fixed at 1.0 for simplicity). We use the same weight-at-age relationship here as was assumed above in the synthesis model.

### Fitting the Synthesis Model to the Simulated Data Sets

For each run the numbers in age categories 6–13+ in the initial year ($N_{6,1}$–$N_{13,1}$), recruitment ($N_{5,1}$–$N_{5,15}$) in each year, four selectivity parameters for the fishery and four for the survey, $F_y$ in each year, and $q$ (the proportionality constant for the survey) were estimated. Of the above, the $F_y$'s and $q$ were determined by constraints, and the others are estimated as formal parameters. Other values used in generating synthetic data and calculating likelihoods either were constants assumed known a priori or were calculated from the formally estimated parameters, parameters determined by constraints, and the assumed constants.

As mentioned above, our estimates of $F_1$–$F_{15}$ and $q$ were obtained by requiring them to satisfy constraints. The $F_y$'s were continually updated along with the formal parameters so that the estimated catch biomass in each year exactly matched the observed catch, if this were possible (Methot 1990). A likelihood component for the catch biomass was included in the fitting so that solutions that did not allow the catch biomass to be matched (e.g., if an $F$ is fixed so that the population cannot support the observed catch) were penalized for this lack of fit through smaller likelihoods. Because the survey is a relative one, the survey proportionality constant, $q$, is chosen so that the sum of the model's estimated survey catches over years equals the observed sum based on the data (Methot 1990).

The set of formal parameter estimates and constrained values that maximized the log-likelihood function was chosen as the best fit (Fournier and Archibald 1982; Kimura 1990; Methot 1990). The log-likelihood ($L$) was

$$(8) \quad L = L_1 + L_2 + L_3 + L_4$$

where $L_1$ was the log-likelihood associated with the fit to the fishery age composition, $L_2$ was the log-likelihood associated with the fit to the survey age-composition data, $L_3$ was the log-likelihood associated with the biomass of fishery catch, and $L_4$ was the log-likelihood associated with the survey index of biomass. These individual components (ignoring constant terms) were

$$L_1 = \Sigma_y\, 400\, (\Sigma_a \tilde{P}_{f,a,y} \log \hat{P}_{f,a,y})$$

$$L_2 = \Sigma_y\, 400\, (\Sigma_a \tilde{P}_{s,a,y} \log \hat{P}_{s,a,y})$$

$$(9) \quad L_3 = \Sigma_y - 0.5 \left\{ \frac{\log\left(\dfrac{\hat{C}_{f,y}}{\tilde{C}_{f,y}}\right)}{\sigma_f} \right\}^2$$

$$L_4 = \Sigma_y - 0.5 \left\{ \frac{\log\left(\dfrac{\hat{C}_{s,y}}{\tilde{C}_{s,y}}\right)}{\sigma_s} \right\}^2$$

where a tilde indicates observed data and a circumflex indicates values estimated by the stock synthesis model. $P_{f,a,y}$ represents the proportion of the sample type $t$ (either fishery ($f$) or survey ($s$) in year $y$ that is age $a$, and $\sigma_t$ indicates the (assumed known) standard deviation on a log-scale of $\bar{C}^{t}_{y}$

$L_1$ and $L_2$, the log-likelihood components for the fishery and survey age compositions, reflect the assumption that the observed proportions-at-age for each year were produced as though the sampled fishery catch or sampled survey catch were multinomial samples of size 400. This "effective sample size" of 400 is internal to the likelihood component and acts to weight the magnitude of the component based upon the assumed precision associated with the sampling program. The value of 400 used here matched the actual sample size used to generate the age-composition data (see above). In practice, an analyst could estimate the effective sample size for each year based on independent information on the precision of the catch sampling program (Methot 1990). Our approach assumed that the effective sample size was constant, and more importantly, that it had been estimated correctly.

The likelihood components for the fishery catch biomass and the survey index were of lognormal form. Thus, the likelihood increased as the squared errors between the log-transformed observed and synthetic values decreased. The values of $\sigma_f$ and $\sigma_s$ were assumed known and act to weight the two components in the total log-likelihood. They were determined by the assumed level of error associated with each type of data. $\sigma_f$ was set at a value corresponding to a CV of 1% on the untransformed scale, which matches the level of error used to produce the observed (simulated) data. $\sigma_s$ was set at values corresponding to CV's of 10, 25, or 50% on the untransformed scale, with the level of error chosen to match the level of error used to produce the observed (simulated) data for the given run.

For interested readers, the next two subsections provide technical detail on the process of searching for the maximum likelihood solution.

### Numerical Details of the Fitting Procedure

The maximum likelihood solution was found using a Broyden–Fletcher–Goldfarv–Shanno update procedure combined with a cutback line search, a standard quasi-Newton method (Gill et al. 1981). Convergence was assumed when both the maximum change in any formal parameter value was less than 0.1% and the total log-likelihood changed less than 0.001%. Initial tests indicated that more stringent convergence criteria did not lead to improved estimates.

Our experience in fitting age-structured models to fishery data has indicated that results can be sensitive to initial parameter values, so we attempted to mimic the approach an analyst might use to specify initial values. Initial numbers at age and recruitment in each year were set by doing a cohort analysis (Pope 1972), following the approach used in Deriso et al.'s (1985) catch-at-age software (CAGEAN). Initial values for parameters determining fishery selectivity were set as follows. First, the $F_{a,y}$'s estimated by the cohort analysis were divided by $F_{y,10}$. These were then averaged over years to obtain an estimate of $s_{f,a}$ for each age, and the double-logistic function was fit to these estimates by least squares. The shape of the survey selectivity function was assumed to be essentially unknown, and a single set of initial values that produced a mildly dome-shaped selectivity function was used in all runs.

### Local versus Global Maxima on the Likelihood Surface

When maximizing a parameter-rich function, there is a real danger that a solution may only maximize the likelihood function locally. This is of special concern in simulation studies because it is generally not practical to simulate the critical review of a stock assessment scientist for each individual run. We found that the model occasionally converged to solutions that did not have the global maximum likelihood. We discovered this by first noting that in some cases the estimated fishery selectivity function was asymptotic, or more rarely flat or decreasing, instead of the correct dome-shape. In a separate set of runs, we examined whether these solutions were true maximum likelihood solutions by fixing the fishery selectivity parameters at the correct values and reestimated the remaining parameters. Cases that originally estimated either a flat or declining fishery selectivity curve showed a substantial increase in the likelihood function, while likelihoods were similar to original values for cases where the original estimated fishery selectivity was either dome-shaped or asymptotic. In some test cases, we did not have success reaching the true maximum likelihood solution by restarting the fitting process from the incorrect solution.

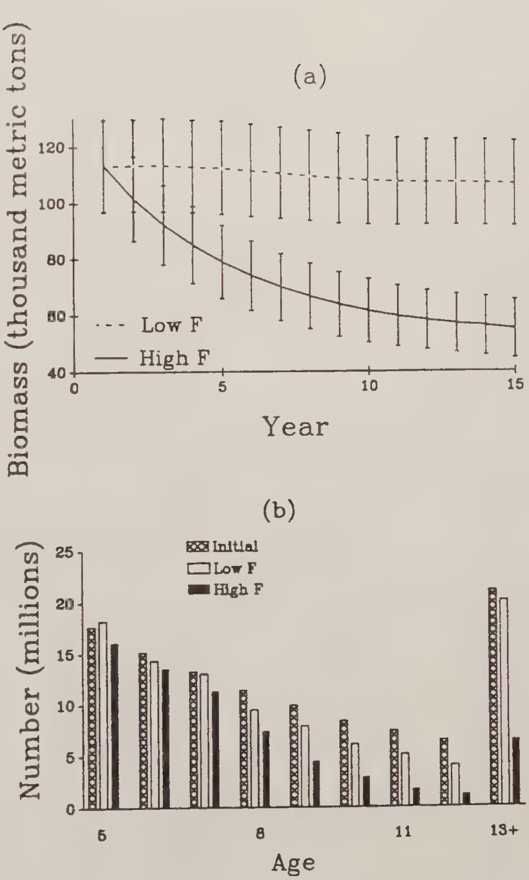

FIG. 2. True population dynamics of simulated populations. (a) Average biomass (± SD) plotted against time for high and low fishing mortality rates and (b) average initial and final numbers-at-age for low and high fishing mortality rates.

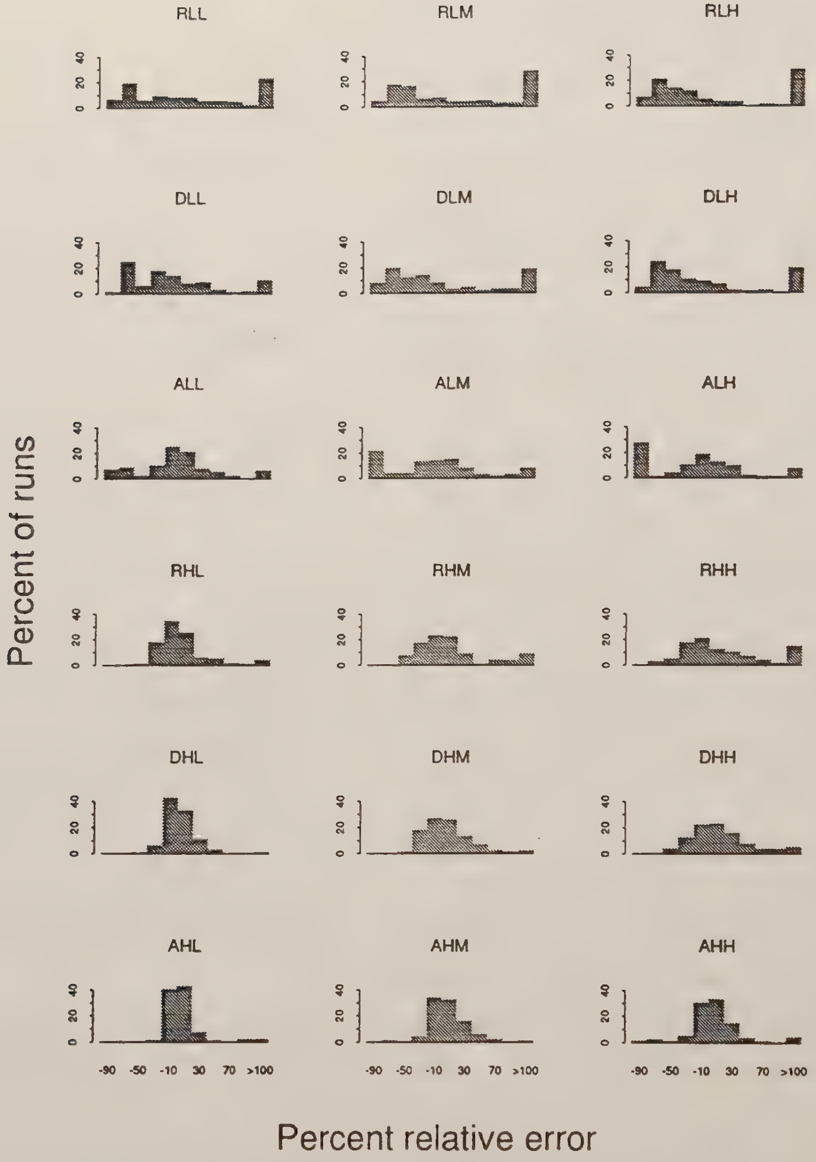

FIG. 3. Distributions of relative errors in estimated year 15 biomass for each case. Headings of the form "XYZ" denote the survey selectivity (X = R, D, or A for recruit, dome-shaped, or asymptotic, respectively), the fishing mortality rate (Y = L for low ($0.075 \cdot yr^{-1}$) or Y = H for high ($0.3 \cdot yr^{-1}$), and the survey coefficient of variation (Z = L, M, or H for low (10%), medium (25%), or high (50%), respectively) for each case.

In real assessments, we expect that declining or flat selectivity curves would be considered suspect, and additional runs would be done with different initial values for the parameters, so that a solution close to the maximum likelihood might be found. A real analyst might also run the stock synthesis model with a grid of starting values and potentially avoid the problem we encountered in the cases described above. We have therefore excluded runs that, by inspection, would be categorized as nearly flat or generally declining. (We defined as nearly flat or declining any case where the estimated fishery selectivity for age- 5 fish was greater than 70% of the maximum estimated selectivity; this is substantially above the true selectivity at age 5, which is 17% of the maximum, and nearly all values over 25% were also over 70%.) Because of the rarity of the "flat" and declining estimated curves (about 5% of the runs), excluding these runs does not influence any of our qualitative con-

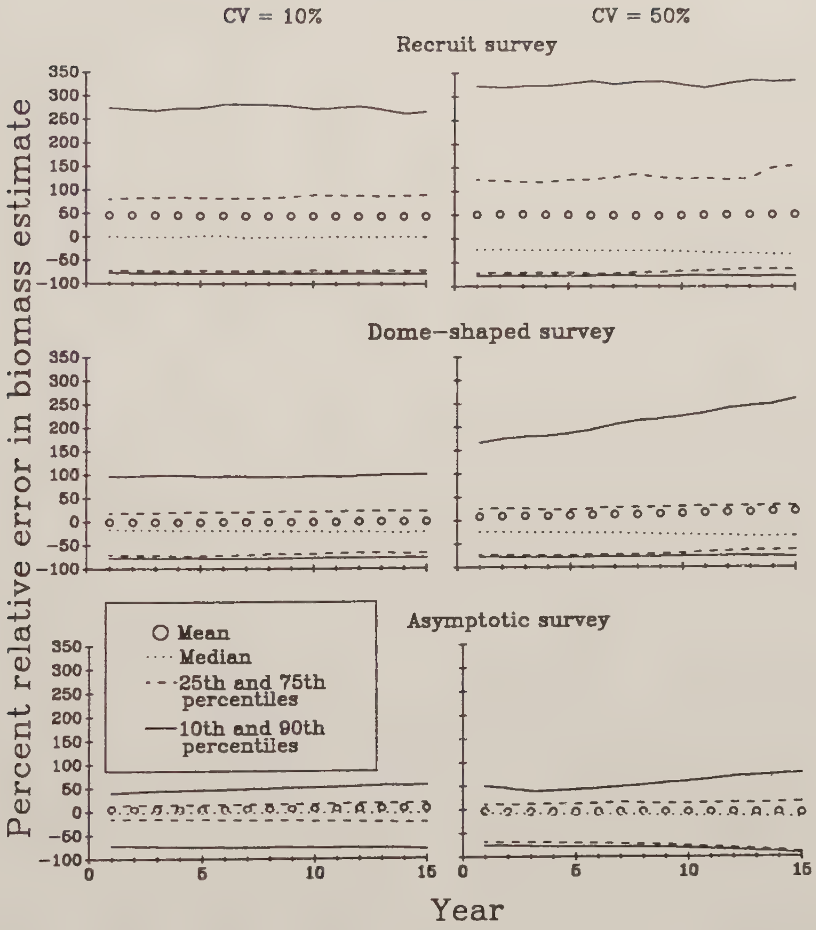

FIG. 4. Relative error in biomass estimates plotted aginst year for the low fishing mortality rate. Shown are results for survey CV's of 10 and 50%. For conciseness, results for survey CV's of 25% are not displayed; they were intermediate between the displayed cases.

TABLE 2. Percentage of runs with estimates of year 15 biomass within 20% of the correct value.

| Survey type | Fishing mortality | Survey variability | | |
|---|---|---|---|---|
| | | Low | Medium | High |
| Recruit | Low | 16.8 | 11.8 | 8.8 |
| | High | 60.6 | 46.1 | 33.7 |
| Dome-shaped | Low | 22.6 | 12.0 | 16.2 |
| | High | 76.0 | 53.0 | 45.5 |
| Asymptotic | Low | 46.2 | 29.2 | 32.0 |
| | High | 84.2 | 66.5 | 64.0 |

clusions. If included, these runs would accentuate the patterns presented below because the cases with the most variable results also produced more estimated flat and declining selectivity functions, and runs with these erroneous selectivity patterns also tended to have large errors in other parameters.

## Results

### Population Dynamics

Under the high fishing rate scenario, average biomass fell by about half from year 1 to 15, and the contribution of the older ages, particularly the 13+ category, declined markedly (Fig. 2). On average, biomass leveled off in the final years of the simulations because the population was coming into balance with the higher mortality imposed by fishing. Under the lower fishing rate, the decline in biomass was only slight, and the shift in the age distribution was not marked.

### Skewed Distribution of Errors

We examined the distributions of percent relative error (PRE) = 100 × (estimated-true)/true for each run both for biomass and recruitment estimates. For each type of survey the distribution of errors was skewed, so that the mean PRE typically exceeded the median (Fig. 3–7). Median errors were typically

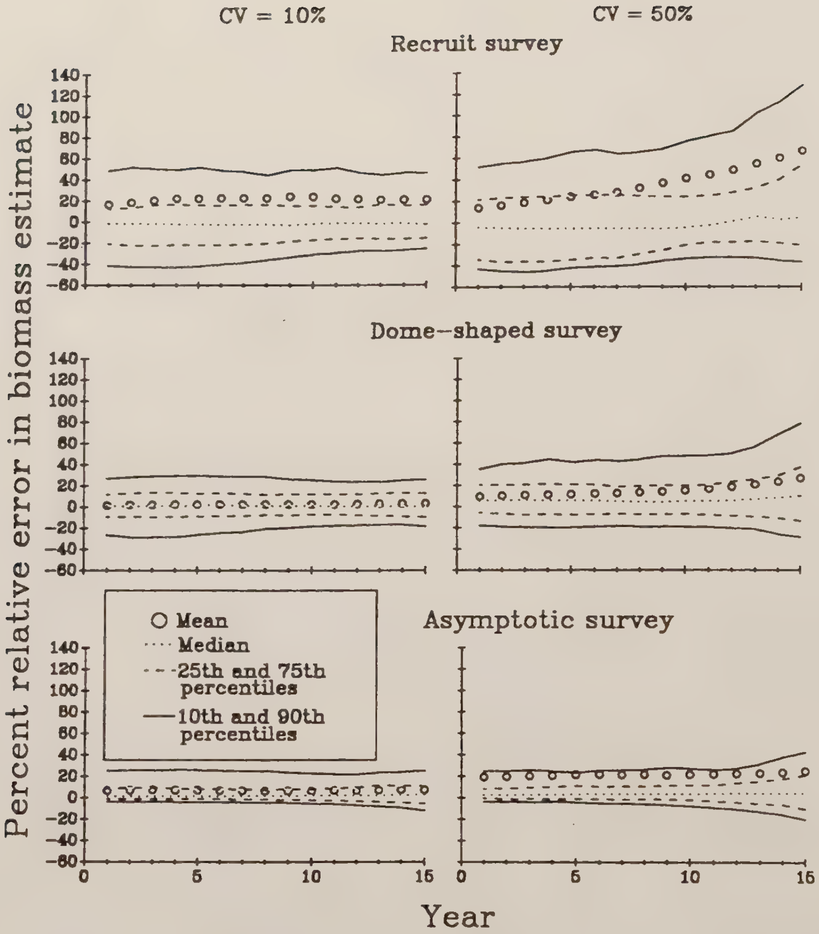

FIG. 5. Relative error in biomass estimates plotted against year for the high fishing mortality rate. Shown are results for survey CV's of 10 and 50%. For conciseness, results for survey CV's of 25% are not displayed; they were intermediate between the displayed cases.

close to zero. Given the variability in the magnitude of errors and the skew of the distributions, it was clear that the mean error alone would sometimes be an insufficient measure of the performance of the stock synthesis model.

### Accuracy and Precision in Biomass and Recruitment Estimates

For management purposes, the accuracy of biomass estimates in the final year of an assessment is usually of greatest interest. Consequently, we examined the distribution of relative errors in estimated biomass in the 15th year (Fig. 3) and also tabulated the percentage of runs with year 15 biomass estimates within 20% of the correct value (Table 2). Although 20% is a somewhat arbitrary cutoff, we felt that stock assessments with errors less than 20% would be classified as successful by most workers. The overall pattern in the results is for greater accuracy and precision given a higher fishing mortality level and when survey precision was higher (Table 2; Fig. 3). Errors were most concentrated around zero for the asymptotic survey and least concentrated around zero for the recruit survey (Table 2; Fig. 3). The difference in accuracy and precision between the recruit and asymptotic surveys was comparable with differences within a survey type when its CV ranged from 10 to 50%. The difference between the asymptotic and dome-shaped surveys was accentuated at a low fishing rate (Table 2; Fig. 3). This latter result is reasonable because the asymptotic survey sampled older fish to a greater extent, and these constituted a larger proportion of the year 15 stock at a low fishing rate (Fig. 2).

Estimates of biomass and recruitment in earlier years are also of interest because they can provide information on how the stock is changing over time. In general, the precision and accuracy of biomass (Fig. 4 and 5) and recruitment (Fig. 6 and 7) estimates over the entire time series showed the same qualitative patterns as year 15 biomass estimates. The most accurate and precise estimates came from the asymptotic survey and the least accurate and precise from the recruit survey. As might be

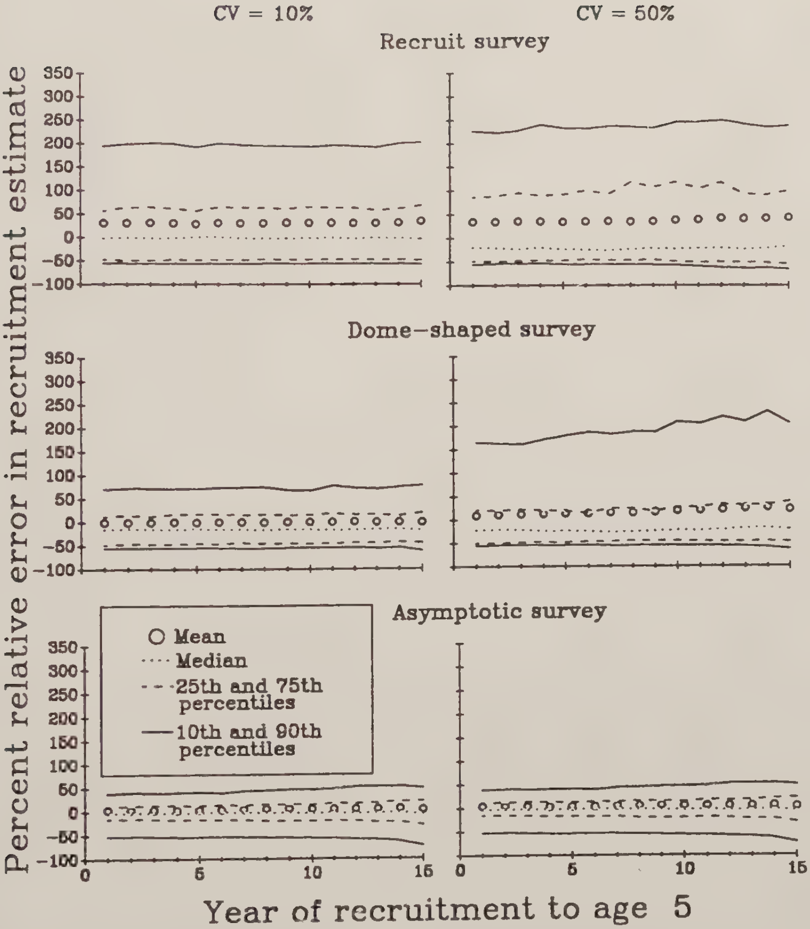

Fig. 6. Relative error in recruitment estimates plotted against year for the low fishing mortality rate. Shown are results for survey CV's of 10 and 50%. For conciseness, results for survey CV's of 25% are not displayed; they were intermediate between the displayed cases.

expected, estimates were better when the survey CV was lower or the fishing mortality rate was higher.

Errors in estimated biomass in year 15 were generally associated with an overall scaling error. These scaling errors caused the correlation between errors in biomass estimates and errors in initial number and recruitment parameter estimates to be high, although the correlations did fall off some at the beginning and end of the time series (Fig. 8). The correlation between errors in recruitment (or initial numbers-at-age) and errors in year 15 biomass estimates tended to be weakest in cases where absolute estimates of biomass were best. For example, correlations were generally lower at the higher fishing mortality rate, especially for the dome-shaped and asymptotic surveys with a CV of 10%.

To the extent that errors were due to an overall scaling problem, estimates of relative year-class strength might still be quite good even when absolute estimates were poor. We measured relative recruitment, on a log scale, as log-transformed recruitment minus the mean of log-transformed recruitment. Estimated and true values of relative recruitment were highly correlated (Fig. 9). Although lower, the correlations were still substantial even at the end of the time series. The lowest correlations were for the dome-shaped survey at the end of the time series of recruitment estimates. This is not unexpected because these year-classes were never well sampled by this survey.

Substantial errors in year 15 biomass were sometimes associated with trends in estimated recruitment, as estimated by linear regression of recruitment estimates against year. Stong trends were most evident when the fishing mortality rate was low, especially when final biomass was substantially overestimated (Fig. 10). For this case, although more trends were positive, some strong trends were negative, and in these cases, biomass in the first year was overestimated to an even greater degree than year 15 biomass. Strong trends were less common at the higher fishing mortality rate, and underestimates tended to have more declining trends and overestimates more increasing trends (Fig. 10).

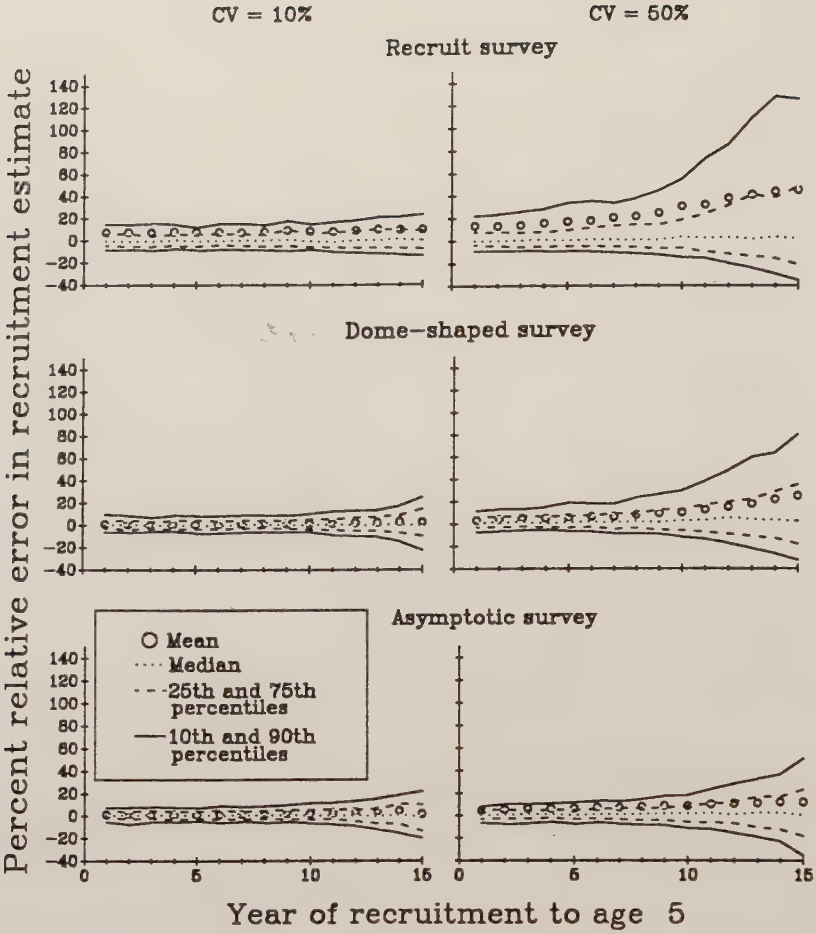

FIG. 7. Relative error in recruitment estimates plotted against year for the high fishing mortality rate. Shown are results for survey CV's of 10 and 50%. For conciseness, results for survey CV's of 25% are not displayed; they were intermediate between the displayed cases.

### Temporal Patterns in Biomass and Recruitment Estimates

By analogy with cohort analysis, it is reasonable to expect convergence of estimated values of recruitment as we move back in time, with the convergence being stronger at higher fishing mortality rates (Pope 1972). To the extent that the convergence property carries over to separable models, and the convergence is toward the true value, we would expect to see tighter distributions of relative errors in estimated recruitment earlier in the time series and at higher fishing mortality rates. Our results match this expectation. At the lower level of fishing mortality, there appears to have been only slight convergence in earlier years toward the correct value of recruitment (Fig. 6). In contrast with the low fishing rate results, there was substantial convergence for estimates of recruitment at the high level of fishing mortality (Fig. 7).

In a number of cases, biomass estimates improved as we moved backward in time (Fig. 4 and 5). This, however, is not a general result. For example, at a high fishing mortality level with a low-variability dome-shaped survey, the most accurate biomass estimates are in year 10, with slightly less accurate estimates in earlier years (Fig. 5). This may have occurred because some of the cohorts contributing to biomass in the early years were observed only for a few years before moving into the 13+ category (see also Kimura 1989).

## Discussion

In this paper, we used Monte Carlo simulation to evaluate the performace of the stock synthesis model. Our study was unique in its assessment of the value of a relative survey (i.e., one proportional to available stock, but with the proportionality constant unknown) to the synthesis model, and especially in the comparison of such surveys with different selectivity patterns. Although we only examined the stock synthesis model in our simulations, we suspect that many of our results apply more generally to statistically based catch-at-age methods such as

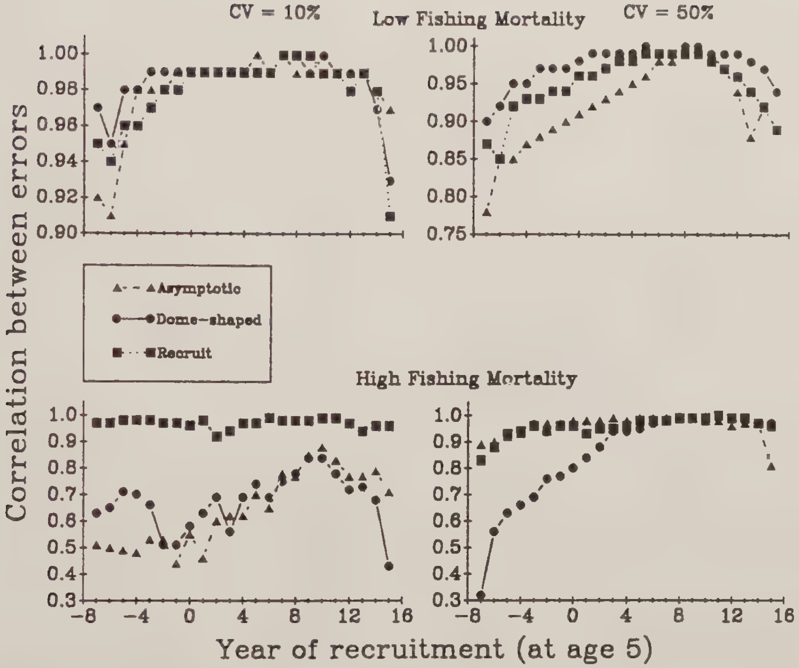

FIG. 8. Correlation between relative error in estimated biomass in year 15 and relative error in estimates of initial numbers-at-age and recruitment parameters. Correlation is plotted against the year of recruitment to age 5 associated with the parameter. Thus, the correlations with recruitment parameters ($N_{5,y}$, $y = 1, ..., 15$) are plotted at $X$ values of $y = 1, ..., 15$, and the correlations with initial numbers-at-age ($N_{a,1}$, $a = 6, ..., 13$) are plotted at $X$ values of $a - 6 = 0, -1, ..., -7$. For example, the correlation between the relative error in estimated year 15 biomass and initial numbers at age 8 ($N_{8,1}$) is plotted at an $X$ value of $-2$ because age 8 fish in year 1 recruited at age 5 3 yr earlier. For conciseness, results for survey CV's of 25% are not displayed; they were similar to displayed results.

CAGEAN (Deriso et al. 1985) and perhaps also to tuned virtual population analysis (e.g., Pope and Shepherd 1985). Care should be taken in extrapolating from our results to short-lived species because the role of survey selectivity could be quite different when the population is composed of only a few age-classes.

Although tangential to the main thrust of this paper, we think that it is of interest that the synthesis estimates of recruitment and biomass were generally positively biased. In contrast with the mean errors, median errors were generally quite close to zero. This kind of "transformation bias" is a well-known phenomenon arising from the skew in the lognormal distribution of errors we assumed. We suspect that such a bias is built into many catch-at-age methods and is probably a real phenomenon because in practice, most distributions of errors will be skewed. However, whether a median or mean error of zero (or something else) is desired depends in part upon management goals (see also Pope and Shepherd 1985).

In our study, an asymptotic survey was best for estimating current stock size within some fixed percentage of the correct value. Accuracy fell some for the dome-shaped survey, and the recruit survey produced estimates that were considerably less accurate than those associated with the other survey types. These results suggest that, all else being equal, an asymptotic survey should be chosen. The extent, however, to which the selectivity pattern of a survey can be controlled or chosen is of pragmatic concern. For example, fish behavior, distribution, and ability to avoid capture may make it difficult to design an asymptotic survey. However, a combination of surveys that together capture a broad range of ages may provide many of the benefits we have associated with an asymptotic survey. In the end, choices among survey types will involve their relative costs, the value of forecasting future recruitment (e.g., Walters 1989), as well as the expected accuracy of the resulting estimates of current biomass. When these trade-offs are being made, it is important to keep in mind that differences in the performance of surveys with different selectivity patterns can be quite substantial, rivaling differences in performance resulting from severalfold differences in coefficients of variation in survey error.

A relative survey can be used to help determine absolute abundance primarily because it provides information on how the fished stock changes from year to year. The magnitude of these relative changes can then be related to the absolute magnitude of the fishery catch. The poor performance associated with the recruit survey can be understood by noting that most fish captured by the recruit survey have not yet experienced fishing mortality. Thus, changes in survey CPUE reflect year-to-year variations in relative recruitment, but are largely uncoupled from changes in the stock due to fishing. Furthermore, the

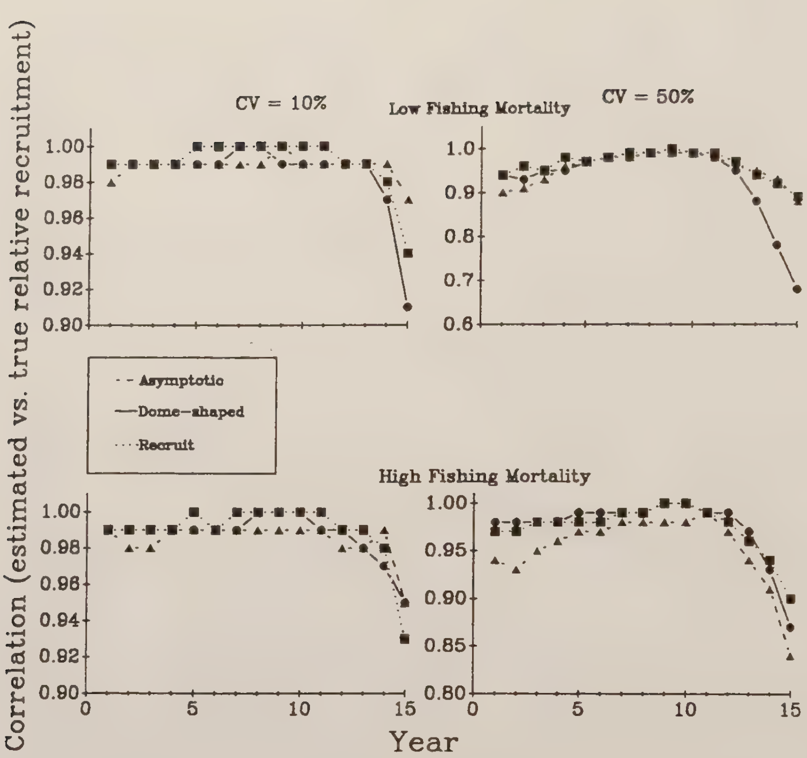

FIG. 9. Correlation between estimated relative recruitment and actual relative recruitment plotted against the year of recruitment. For conciseness, results for survey CV's of 25% are not displayed; they were similar to displayed results.

fishery age-composition data alone already contain substantial information on relative year-class strength (e.g., Ricker 1975, p. 265–272), but essentially none on absolute stock size (Doubleday 1976; Deriso et al. 1985; Shepherd and Nicholson 1986). Consequently, much of the information on relative year-class strength provided by the recruit survey is redundant and does not provide information on absolute abundance. Indeed, for the recruit survey, our stock synthesis estimates of relative recruitment were quite good, even though absolute estimates of recruitment and biomass tended to have large errors.

When fishing mortality has been low, assessments of current stock size based on fishery catch-at-age data and a survey of relative abundance will often be substantially in error. Under higher cumulative fishing mortality, it is intuitive that catch-at-age analyses give better results because such a large proportion of each cohort of fish are counted in the catches (Pope 1972). However, our results suggest that even when $F$ is high, the relative survey must be highly precise to have a high probability that an estimate of current abundance will be within 20% of the correct value. Although large errors in estimated year 15 biomass were sometimes associated with incorrect patterns for the fishery selectivity function in our study, most of the estimated patterns were not "pathological," and we doubt that an analyst could rule them out as unreasonable without making use of information external to the assessment. With a very long time series, a relative survey might fix absolute abundance adequately, even at a low fishing mortality rate, but then the assumptions of constant natural mortality, selectivity patterns, growth, etc., are probably untenable (e.g., Walters 1986).

We believe that our simulation study presents a best-case scenario for stock assessments. In the simulations, selectivity or weight-at-age did not change over time, natural mortality was assumed known and remained constant (over years and ages) at the assumed value, and catch biomass was assumed to be known accurately. The precision of our simulated survey varied from high (CV = 10%) to modest (CV = 50%), and we assumed that there was a survey every year. In practice, the real population will deviate from the synthesis (or other) model to an unknown extent, and the quality and quantity of data will often be lower than in our simulations.

To place our simulations in context, it is worth considering the actual kinds of data usually available for use with the stock synthesis model. Assessments of several groundfish stocks on the west coast of North America make use of trawl survey data collected every third year with CV's near 50% (Bence and Rogers 1992; Rogers and Bence 1992). For many stocks, natural mortality was estimated by catch curves, maximum ages, or simply by analogy with other species (e.g., Hightower and Lenarz 1986; Bence and Rogers 1992; Rogers and Bence 1992). In our simulations, we generated data with a very low level of sampling error for catch biomass because this is the assumption under which the synthesis model is fit to the data. However, we recognize that catch biomass estimates are probably less accurate than the low level of error built into our simulations

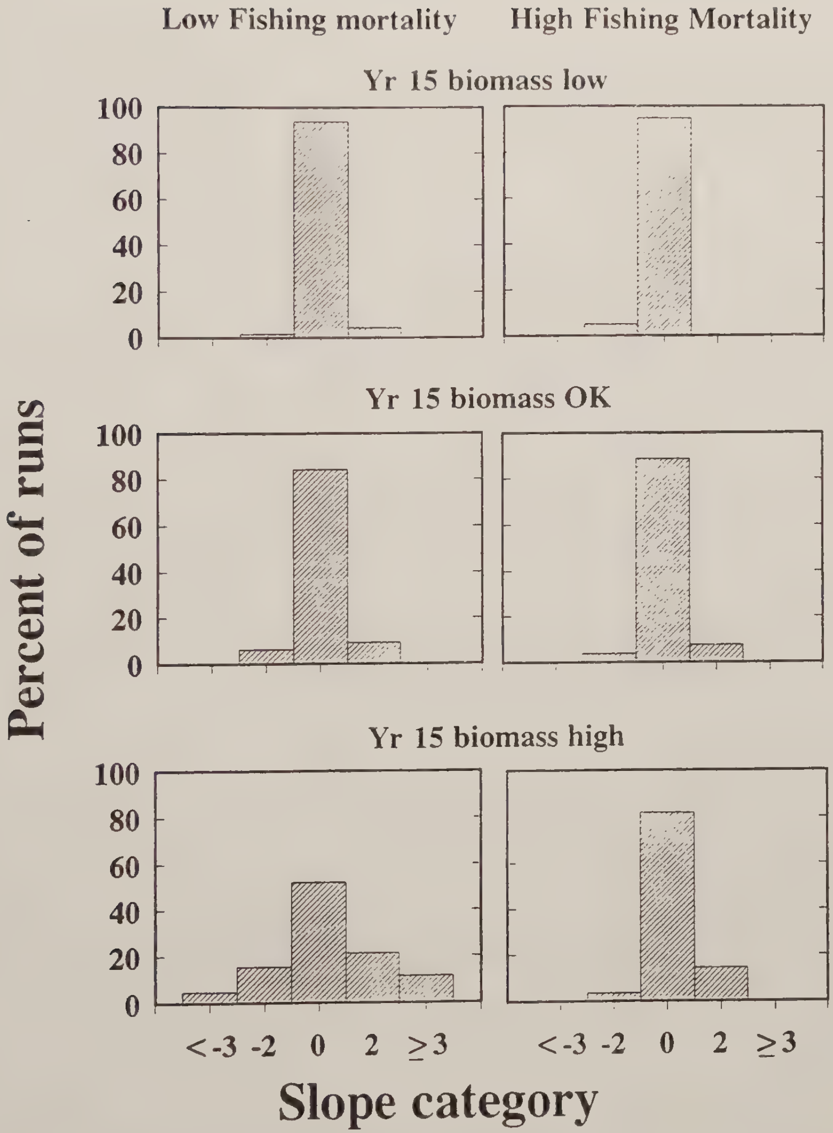

FIG. 10. Distribution of estimated slopes (by linear regression) of the trend in estimated recruitment over time. Distributions were calculated separately for replicates with low (more than 20% low), OK (within 20% of the correct value), or high (more than 20% high) estimates of year 15 biomass. Shown are results for an example low and high fishing mortality case (dome-shaped selectivity, CV = 25%); other cases showed similar patterns.

because of two general problems. First, discard levels generally are estimated roughly from an observer program of restricted spatial and temporal extent. Thus, even when landings are made in nearly pure "market categories" and reported landings are essentially a census of the landed catch, as they are for widow rockfish, the error in catch biomass could be substantial. Second, estimation of landed catch is complicated for some stocks because landings are made in mixed-species market categories that need to be sampled (Bence and Rogers 1992). This can sometimes cause the estimates of landings to have substantial sampling error. For most assessments using the synthesis model, age-composition data appear to be quite good, at least as representations of the landed catch. Estimated proportions at age in the landed catch often come from extensive sampling at the ports (stratified both spatially and by time of year) combined with the reading of thousands of otoliths.

**Abstract:** Planktonic young (paralarvae) of *Ommastrephes bartramii*, have recently been found in early spring (March-May) along the Hawaiian Archipelago. Statoliths of paralarvae ($N = 57$) sampled in February 1991 were used to estimate ages, hatch dates, and growth rates. Growth increments within statoliths were enumerated using light and scanning electron microscopy. Under the assumption that increments were formed daily, paralarvae were estimated to grow exponentially for at least 35 days post-hatching. Based on the growth model, paralarvae 15, 25, and 35 days old had estimated mantle lengths of 1.6, 4.3, and 12.1 mm, respectively. The paralarvae were estimated to have hatched between 1 and 25 January 1991, based on back calculation of statolith increments from the time of capture.

## Introduction

Events occurring during the early life history of squids may profoundly influence their recruitment, for squids are presumably most susceptible to natural mortality during embryonic and paralarval development. The dominant sources of natural mortality in the early life history of marine fishes, and presumably squids, are a combination of density-dependent factors, such as starvation (Lasker, 1975) and predation (Houde, 1987), and density-independent factors, such as temperature and oceanic transport to unfavorable areas (Bailey, 1981; Parrish *et al.*, 1981). Recruitment may be especially influenced by paralarval growth rates which may determine the duration of the paralarval stage: Small declines in paralarval growth rates could result in a longer planktonic period during which high mortality rates are presumed to operate.

Daily growth increments in squid statoliths provide a method for precisely determining the ages, growth rates, and hatch dates of squid from the field. Increment counts have been used to estimate the ages of several squid species and life history stages (see review by Rodhouse and Hatfield, 1990). The daily nature of growth increments has been verified, through laboratory studies, to occur in a variety of teuthoid and sepioid species (e.g., Dawe *et al.*, 1985; Lipiński, 1986; Yang *et al.*, 1986; Jackson, 1989; Nakamura and Sakurai, 1990; Bigelow, 1992), although the physiological mechanisms responsible for increment formation remain obscure (Morris, 1988) Estimation of hatch dates, back calculated from ages at the time of collection, can define periods of successful spawning. Spawning sites may be identified from hatch dates in conjunction with physical data on the rate and direction of ocean currents.

*Ommastrephes bartramii*, is an abundant squid in the subtropical-temperate Pacific Ocean. Since the reduction in stocks of the squid *Todarodes pacificus* in the early 1970's, North Pacific stocks of *O. bartramii* have been targeted by a Japanese jig fishery and by an international driftnet fishery composed of fishermen from Japan, Korea, and Taiwan. Japan's annual catch of *O. bartramii* ranged from 100,000 to 215,000 metric tons between 1981 and 1989, with approximately 80% of the catches taken by the squid driftnet fishery (Murata, 1990; Yatsu *et al.*, in press).

Growth of *O. bartramii* has been estimated from analysis of length-frequency distributions of sequential samples from the jig and driftnet fisheries (e.g., Murakami *et al.*, 1981; Murata *et al.*, 1988). These studies suggest that North Pacific populations are composed of winter and spring cohorts, with a life span of approximately 12–18 months for females and 12 months for males.

*Ommastrephes bartramii* paralarvae are known to occur in two geographical areas: southeast of Honshu, Japan (ca. 35°N, 140°W: Okutani, 1968; 1969), and along the Hawaiian Archipelago (Hayase, 1989; Young and Hirota, 1990). Paralarvae occur in waters off Japan during January, March, April, and May (Okutani, 1968, 1969) and in waters off the Hawaiian Archipelago from at least February to May (Hayase, 1989; Young and Hirota, 1990; R.E. Young pers. comm.). Vertical distribution data suggest that *O. bartramii* paralarvae typically occur at the surface and at 0–40m depth during day and night (Okutani, 1968; Young and Hirota 1990).

Our study examined the growth increments within statoliths of field-caught *O. bartramii* paralarvae (2.1 to 13.7 mm mantle length (ML)) from Hawaiian waters. Using age and hatch-date estimates based on enumeration of growth increments, we estimated paralarval growth rates, defined the periods of successful spawning, and drew inferences about the duration of the paralarval period.

## Materials and Methods

### *Paralarval collections*

*Ommastrephes bartramii* paralarvae were collected during synoptic plankton surveys within 100 nmi of the Hawaiian Archipelago in February 1991 with the NOAA ship *Townsend Cromwell* and the Hokkaido University ship *Hokusei-Maru*. Sampling gear consisted of a 4-$m^2$ ring net, 0.8-$m^2$ ring net, and a Manta neuston net (0.49-$m^2$ mouth)—all with 505 $\mu$m mesh. Oblique tows to approximately 100m were taken with the 4-$m^2$ ring net, and surface tows were taken with the 0.8-$m^2$ ring and Manta nets (Table 1). Paralarval squid were sorted from the plankton on board ship with stereomicroscopes; they were immediately fixed in 95% ethyl alcohol or 99% isopropyl alcohol. Mixed layer temperatures were obtained at each station from conductivity-temperature-depth casts to 1,000m or expendable bathythermograph casts to 700m.

### *Laboratory procedures*

Paralarvae from four locations were used for statolith examination (Table 1). Paralarval identifications followed Young and Hirota (1990) and were confirmed by R. E. Young (University of Hawaii). Dorsal ML and proboscis length of each paralarva was measured to the nearest 0.1 mm with an ocular micrometer and a stereomicroscope. Both statoliths were extracted from the paralarva and placed on microscope slides, then rinsed with distilled water and allowed to dry. Statoliths were mounted in clear resin (Eukitt or Petra-epoxy) with the anterior (concave) side positioned upward. The terminology of Clarke (1978) and Lipinski *et al.* (1991) are used to describe statolith external features and microstructures. Statolith dimensions of focus-dorsal dome length, focus-rostral length, and total length between the dorsal dome and rostrum were measured with an ocular micrometer and compound microscope to the nearest 2 $\mu$m. Microstructural examinations were made with a research-quality compound microscope with transmitted light at magnifications of 600–1500×. Whole statoliths from small ($\leq$6 mm ML) paralarvae were viewed with no further preparation, while statoliths from large (>6 mm ML) paralarvae were ground and polished prior to microscopy to improve increment resolution. Grinding was done by hand rubbing the embedded statolith against fine-grained (1200 grit) sandpaper. The statolith was then polished with 0.3 $\mu$m alumina-silica polishing powder.

For some paralarvae, one statolith of the pair was examined with scanning electron microscopy (SEM) to validate observations made with light microscopy. The lateral dome was ground until the focus was at the ground surface. The surface was polished, etched with 0.1% EDTA for 5–20 minutes, and coated with gold in a vacuum evaporator. Statolith microstructures were viewed and photographed with a Hitachi S-800 SEM at various magnifications (700–5,000×).

An increment under light microscopy consisted of a wide, light ring and a narrow, dark ring, while

an increment under SEM. appeared as a wide, lightly etched area (light ring) and a narrow, deeply etched area (dark ring). For each microscopy method, statolith increment counts were made independently by each author at four separate reading sessions.

## Results

Microstructural examination revealed a conspicuous, dark, elliptical zone in the interior of all statoliths under light and SEM (Figs. 1–3). Under SEM, the long axis of the ellipse averaged 21.8 $\mu$m (SD = 3.4 $\mu$m, $N = 17$), while the short axis averaged 17.4 $\mu$m (SD = 2.8 $\mu$m, $N = 17$). This distinctive zone was postulated to be the statolith size at hatching or natal size, because of the similarity in size to *Illex illecebrosus* (Balch *et al.*, 1988) and *Abralia trigonura* (Bigelow, 1992). In the microstructural examination, two features influenced increment enumeration. Weak increments were present between more typical increments on the dorsal dome in a zone of progressively increasing increment width. Increments bordered by distinct, deeply etched, dark rings were presumed to be daily (Fig. 4A), while subdaily increments were defined by faint, shallowly etched, dark rings (Fig. 4B). A second feature influencing increment enumeration was about a 10- to 15-$\mu$m area, immediately distal to the natal ring, that lacked any consistent structuring (Fig. 3). As a matter of convention, increments were enumerated based on continuity of increment width with adjacent increments. The magnitude of the count bias associated with unresolved growth increments appeared to be small, because increment widths of 3-4.5 $\mu$m were extrapolated over an unresolved area of 10–15 $\mu$m. Interpretation of the remainder of the statolith was largely unambiguous. In both microscopy methods, increments were always enumerated from the natal ring to the lateral dome (Figs. 1–2), as statolith orientation was not sufficient to allow increment counts on the rostrum or dorsal dome.

Statoliths were examined with light microscopy from 57 paralarvae of 2.1–13.7 mm ML. A paired $t$-test showed a significant difference between the mean increment counts of the two readers ($p < 0.05$). Mean difference between readers was 2.6 increments. For both readers, no significant difference was found between mean counts of paired statoliths from the 47 paralarvae in which both statoliths were extracted (one-way analysis of variance, $p > 0.05$).

Statoliths from 24 paralarvae were examined with SEM. Mean difference between readers was 0.9 increments. Contrary to mean increment counts from light microscopy, there was no significant differ-

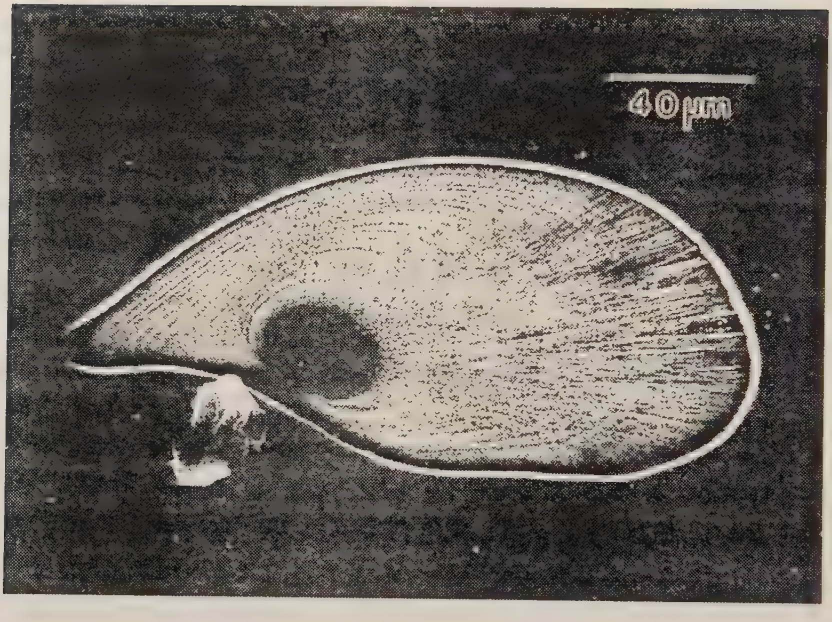

**Fig. 2.** *Ommastrephes bartramii.* Scanning electron micrograph of a ground and etched statolith from a 2.5 mm mantle length paralarva used for increment enumeration.

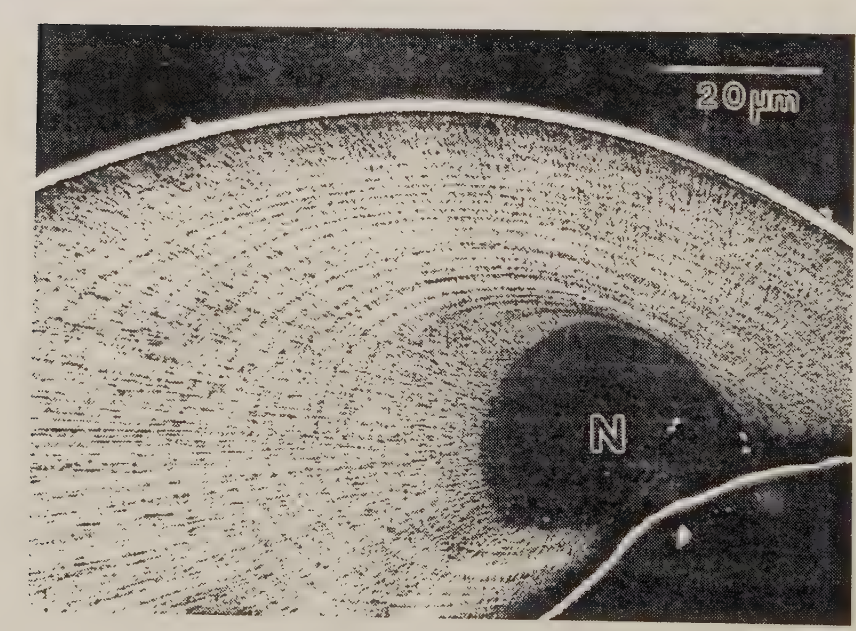

**Fig. 3.** *Ommastrephes bartramii.* Scanning electron micrograph of a ground and etched statolith from a 5.0 mm mantle length paralarva, which demonstrated a nucleus (N).

ence between mean SEM counts of the two readers ($p > 0.05$). No significant difference was found between pooled increment counts from light microscopy and SEM ($p > 0.05$). Differences in increment counts between readers were greater with light microscopy compared to SEM, because under light microscopy, microstructures around the natal zone were difficult to resolve and subdaily increments were more prominent.

For each paralarva, increment counts of both readers made with light microscopy were averaged for analysis of growth in length. An increase in squid size and increment number resulted in an increase in all statolith dimensions (Fig. 5A-B). Increment at length data were pooled over all stations and the following exponential model was fit to the data:

$$ML = 0.331e^{(0.103x)}$$

where ML is in millimeters and $x$ equals the mean increment count (Fig. 6). Nonlinear regression parameters were estimated by least-squares methods. Coefficient of determination ($r^2$) was 0.92. Deviations from the model included individual variability in growth of a paralarva, error in ML measurements, and error in increment counting. Residuals exhibited no conspicuous systematic deviation from linearity by sampling site and no marked increase in variance with age. There were too few samples to test for differences in growth rates between stations. Based on the growth model, paralarvae at an age of 15 days post-hatching (1.6 mm ML) grew at a rate of 0.16 mm·day$^{-1}$, whereas the growth rate of 35-day-old paralarvae (12.1 mm ML) was 1.25 mm·day$^{-1}$ (Table 2). Paralarval length at time of hatching was estimated to be 0.33 mm ML.

The proboscis of *O. bartramii* started dividing by about 6 mm ML (Fig. 7). Proboscis division was completed between 9.5 and 12.0 mm ML, which corresponds to an age range of 32–35 days.

Hatch dates were back calculated through the subtraction of the paralarval age from the date of collection, and were pooled into 3-day periods (Fig. 8). Samples were not pooled because paralarvae were collected with different net types over a large geographical area. The hatching period was 1–25 January 1991. At stations B, C, and D, paralarval hatch dates occurred over a narrow range of 8 days, while paralarvae sampled at station A hatched over a period of 16 days. Paralarvae collected at stations B and D had similar hatch dates (12–19 January 1991).

## Discussion

Analysis of statolith microstructures allowed us to realistically estimate the growth and hatch dates of

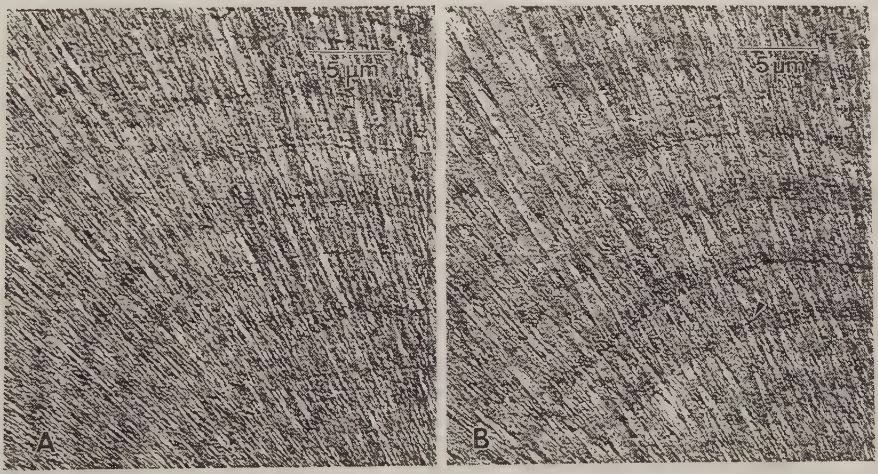

**Fig. 4.** *Ommastrephes bartramii.* Scanning electron micrograph of increments within a statolith. (A) Daily increments were bordered by deeply etched, dark rings. (B) Subdaily increments were composed of faint, shallowly etched, dark rings (arrow).

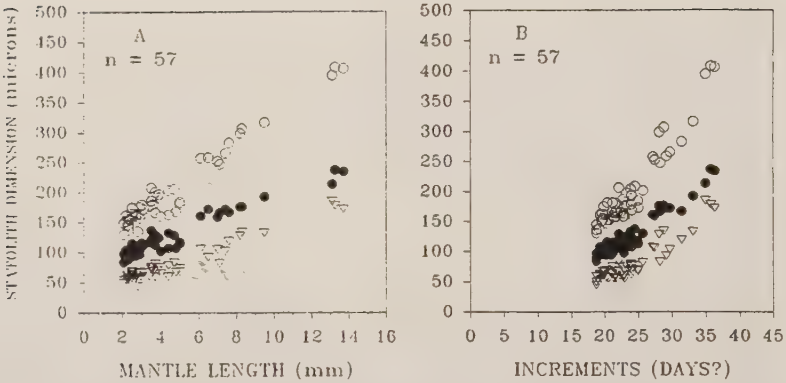

**Fig. 5.** *Ommastrephes bartramii.* Relationship between (A) statolith dimensions and mantle length of paralarvae, and (B) statolith dimensions and number of growth increments (open circles indicate statolith total length; closed circles, focus-dorsal dome length; and triangles, focus-rostral length).

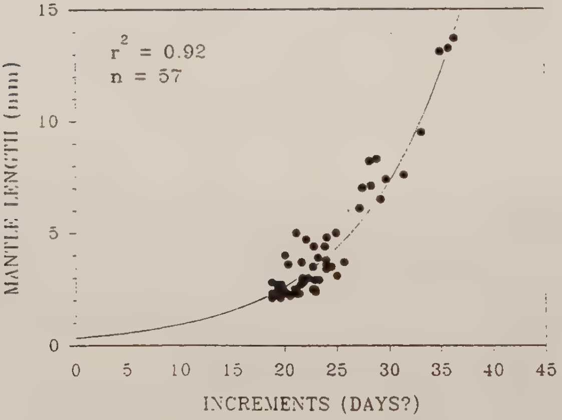

**Fig. 6.** *Ommastrephes bartramii.* Relationship between mantle length and number of increments in statoliths. Exponential growth curve was based on increment counts from statoliths of 57 specimens viewed with light microscopy.

*O. bartramii* paralarvae. A primary assumption of statolith microstructural analysis is that growth increments are formed daily. Growth increments of *O. bartramii* paralarvae are assumed to be daily, based on the similarity in increment appearance in previous studies that validated the frequency of increment deposition (e.g., Dawe *et al.*, 1985; Bigelow, 1992). Validation experiments are impossible at present because eggs, presumably laid in masses, have never been captured and field-caught individuals are not amenable to statolith marking experiments for they perish quickly in captivity. Although we did not validate the frequency of increment deposition, previous studies have for two orders of cephalopods (Teuthoidea and Sepioidea) (e.g., Dawe *et al.*, 1985; Lipiński, 1986; Yang *et al.*, 1986; Jackson, 1989; Nakamura and Sakurai, 1990; Bigelow, 1992), which suggests that daily increment formation may be common to many cephalopod species. However, the existence of subdaily increments in *O. bartramii* statoliths and other squids (Jackson, 1990; Bigelow, 1992) may be a potential source of error if im-

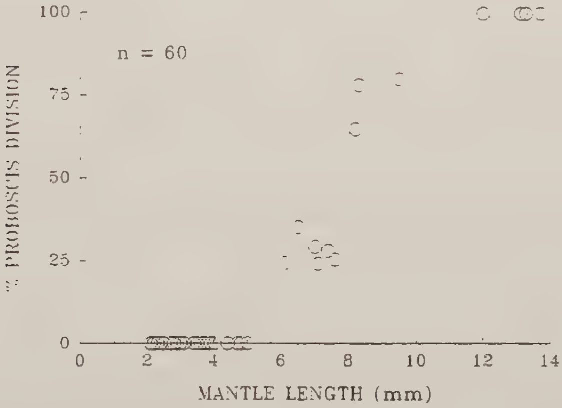

**Fig. 7.** *Ommastrephes bartramii.* State of proboscis division by mantle length.

properly interpreted. A second source of error in interpretation is the presence of an area immediately distal to the natal zone which lacked any consistent structure. Difficulty in resolving increments near the natal ring has been documented for a number of squid species (e.g., Dawe *et al.*, 1985; Jackson, 1989; Bigelow, 1991). Presumably, this ambiguous area corresponds to the yolk stage within early life history. Cues for increment deposition, such as feeding cycles, may not be as strong in the yolk stage and may result in poorly defined increments.

Paralarval growth in length of various squids typically conforms to exponential equations (e.g., Balch *et al.*, 1988; Forsythe and Hanlon, 1989; Bigelow, 1991). Paralarval growth in length of *O. bartramii* is also characterized as exponential for at least 35 days post-hatching. The derived estimate of hatching size (0.33 mm ML) from the growth model is probably underestimated. Although the hatching size of *O. bartramii* is unknown, the size may be approximately 1 mm ML, because other confamilial species are known to hatch at this size [*Todarodes pacificus*, 1.2 mm ML (Hayashi, 1960); *Illex illecebrosus*, 1.2 mm ML (O'Dor *et al.*, 1982)], and Young and Hirota (1990) captured a yolk-stage paralarva which was approximately 1.0 mm ML. In the future, smaller (1–2 mm ML) paralarvae may be captured, and age at length estimates may provide a model which extrapolates to a realistic estimate of ML at hatching.

Our paralarval growth rates are comparable to growth estimates of confamilial species. Paralarval growth derived from statolith analysis has been estimated for *I. illecebrosus* captured from the Gulf Stream off Florida (Balch *et al.*, 1988) and *Stenoteuthis oualaniensis* from Hawaiian waters (Bigelow,

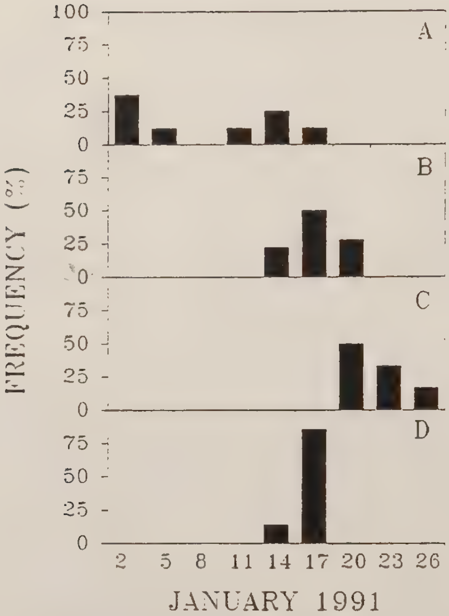

**Fig. 8.** *Ommastrephes bartramii.* Hatch-date distributions derived from examination of statolith microstructures. Stations A, B, C, and D correspond to collection sites in Table 1.

1991). The ML at age estimates were modeled for the three species (Table 2). Though temperature and food effects are unknown, *O. bartramii* paralarvae grew the fastest, while *I. illecebrosus* and *S. oualaniensis* paralarvae grew at similar rates. Since temperature can affect paralarval growth rates (Forsythe and Hanlon, 1989), an age- and temperature-based growth model similar to that recently developed for fish larvae (Campana and Hurley, 1989) could be applied in future comparisons of paralarval growth rates.

The paralarval stage of the Ommastrephid family is classically considered to end with the division of the proboscis to separate the tentacles and is therefore referred to as the rhynchoteuthion stage. A change in statolith growth axes has been postulated to coincide with a transition in life history stages of some squid (Morris and Aldrich, 1985; Bigelow, 1992). For *I. illecebrosus*, the splitting of the proboscis is complete by 8–10 mm ML (O'Dor, 1983). Based on a change in statolith form at about 50 mm ML, Morris and Aldrich (1985) suggested that the paralarval stage extends beyond the rhynchoteuthion stage in *I. illecebrosus*. For *O. bartramii*, the division of the proboscis is complete at 9.5–12.0 mm ML, though there was no change in statolith dimensions at the end of the rhynchoteuthion stage. Therefore, we concur with Morris and Aldrich (1985) in suggesting that the paralarval stage of *O. bartramii* may extend beyond the rhynchoteuthion stage.

The ages of *O. bartramii* paralarvae in our study indicate a hatching period between 1 and 25 January. *Ommastrephes bartramii* paralarvae (6–8 mm ML) have been captured from Hawaiian waters as late as 5 May (Hayase, 1989). Assuming a growth rate similar to the present study, the paralarvae sampled by Hayase (1989) would have hatched between 5 and 7 April. The apparently protracted spawning period concurs with present theories (see review by Murata, 1990) that North Pacific stocks of *O. bartramii* are composed of cohorts spawned during winter and spring.

Statolith analyses are invaluable to ecological and population studies, as they supply the cephalopod biologist with a technique to resolve life history information on a daily level. Future studies with larger sample sizes of *O. bartramii* paralarvae may reveal the environmental conditions which are favorable for paralarval growth and survival.

## Acknowledgements

We thank the captains and crews of the NOAA ship *Townsend Cromwell* and the Hokkaido University ship *Hokusei-Maru*. We especially acknowledge R. Seapy and J. Constantinou who provided the *Hokusei-Maru* specimens and R.E. Young for assistance in paralarval identification and helpful suggestions on an early version of the manuscript. We also thank J.A. Wetherall and an anonymous reviewer whose comments and criticisms contributed to the manuscript.

# Fisheries and Marine Resources of Hawaii and the U.S.-associated Pacific Islands: An Introduction

GEORGE W. BOEHLERT

## Introduction

Fisheries of Hawaii and the U.S. insular Pacific are quite different from typical industrial and recreational fisheries of the mainland U.S. Fisheries productivity in coastal waters of these tropical and subtropical islands may be similar to that in temperate continental shelf-slope fish communities (Marten and Polovina, 1982), but the higher species diversity results in more diverse, lower volume fisheries. Larger, commercial fisheries are often dependent upon deep water, slope-dwelling species or the highly migratory pelagics such as tunas and billfishes. Although land masses in this region are small, the U.S. Exclusive Economic Zone (EEZ) surrounding the island areas is immense, covering over 2 million square miles. Over this broad geographic expanse, a variety of cultural differences affect fishing practices, and even those practices present today are significantly different from the native approaches to fishing methods in Hawaii (Smith, 1993) and Guam (Hensley and Sherwood, 1993). Finally, variations in the population size and in the fishing pressure on the nearshore ecosystem are marked among islands, from the highly populated island of Oahu in Hawaii to sparsely populated islands elsewhere to the mostly uninhabited islands of the Northwestern Hawaiian Islands (NWHI) and Commonwealth of the Northern Mariana Islands (CNMI).

The objective of this volume is to describe our current knowledge on the varied fisheries of Hawaii and the U.S.-associated islands of the Pacific. This introductory paper provides some general background on fisheries in the region.

## Diversity of Fisheries

In the U.S. insular Pacific, the combination of highly complex habitats, high species diversity, and both native and newly introduced cultural practices leads to a diversity of fisheries unparalleled in most other parts of the U.S. Many fisheries are unique to certain localities, such as that for palolo worm in American Samoa (Craig et. al., 1993), seasonal juvenile fisheries for rabbitfish in Guam (Hensley and Sherwood, 1993), and limpet, or opihi fisheries in Hawaii (Smith, 1993). Others are common to all islands, such as the seasonal fisheries for juvenile bigeye scad in all areas. The adults of these coastal pelagics, known as akule in Hawaii or atule in American Samoa, represent the largest volume fishery in nearshore waters but are poorly known in terms of their resource potential. Nearshore reef resources are often overexploited in populated areas, a problem perhaps characteristic of tropical reef fisheries in general (Ferry and Kohler, 1987).

## Evolution of Fisheries

With increasing population, changing cultural composition, and advancing technology, island fisheries have changed in many ways. Prior to western colonization, indigenous peoples of the islands depended on the marine environment and had developed a unique knowledge of marine resources and varied approaches to conservation and management. The cultural impacts of colonization of the islands by non-indigenous peoples had marked effects and typically led to the decline of traditional conservation measures (Johannes, 1978); a concise description of how this happened in Belau, in the Western Caroline Islands, is provided by Johannes (1981). In Guam, Spanish persecution of Chammorros led to the demise of the traditional fishing methods in the mid-1500's (Hensley and Sherwood, 1993). Similarly, in Hawaii, it led to the decline of the traditional management regime of the native Hawaiians that had long protected nearshore resources (Smith, 1993). Trends in the fisheries of Hawaii are perhaps the most pertinent to examine, for the greatest changes have occurred there and these may serve as a warning of what may come in the other island areas as populations increase there as well.

George Boehlert is with the Honolulu Laboratory, Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA, 2570 Dole St., Honolulu, HI 96822-2396, and the Joint Institute for Marine and Atmospheric Research, University of Hawaii, Honolulu, HI 96822. Mention of trade names or commercial firms does not imply endorsement by the National Marine Fisheries Service, NOAA.

---

*ABSTRACT — The fisheries of Hawaii and other U.S.-associated islands in the Pacific Ocean are characterized by high diversity, both in the species exploited and the human cultures that exploit them. The commercial sector has undergone rapid growth in recent years, but recreational and subsistence sectors remain important. Information on these fisheries is generally not available in published form. This paper presents an overview and introduction to a volume of papers describing fisheries in the region, with the goal of making the information available to scientists and the general public. A great deal remains to be learned about the dynamics of these fisheries as well as the associated issues in biological research, fisheries management, and environmental protection.*

Temporal trends of fisheries differ markedly. Shomura[1] described the differences in fisheries of Hawaii between 1900 and 1986, the early period based upon a comprehensive data collection scheme and subsequent analysis by Cobb (1902) and the later period upon State of Hawaii commercial fishery data collection systems. While the two data sets are not identical in coverage, they provide useful comparisons. The total catch nearly doubled in the period considered. Shomura[1] noted several important trends related to the distance of the fishery from shore. Catch of coastal species declined by about 80%, while those of neritic-pelagics (akule, opelu) declined by 40%. Catch of slope and seamount species increased by 80%, whereas manyfold increases in offshore pelagics catch were evident.

It is likely that the decline of nearshore fisheries is based largely upon two factors. First, increasing population and improved fishing technology led to overfishing in the absence of effective management and regulations. Gillnet use, for example, is largely unrestricted, and this can have negative impacts on coral reef fish populations (Gobert, 1992). Similar concerns are expressed about this gear in Guam (Hensley and Sherwood, 1993). Second, habitat destruction from coastal development leads to a decline in availability and quality of critical habitat area needed to support the reef populations. This was most evident for species utilizing fishponds, a habitat which may be similar to estuaries for enhancing juvenile fish production. The decline of the numbers and function of fishponds in Hawaii has been dramatic. Cobb (1902) documented the use of fishponds in his survey of fisheries of Hawaii and even then noted a marked decline in the numbers of functioning fishponds. While the reasons may differ, declining nearshore catches in American Samoa over the last two decades (Craig et al., 1993) are also a concern.

Significant growth in several fishery sectors of Hawaii has been based upon improved technology and an expanded potential geographic range of fishing. The combination of increased catch and targeted high-value markets led to a doubling of the ex-vessel value of Hawaii fisheries from 1970 to 1990 (Pooley, 1993a). Insular fisheries moved to increasingly deeper water, and technology allowed the expansion of the slope fishery in the main Hawaiian islands during the middle of this century. As these fisheries approached full exploitation, the resource potential of the NWHI was examined by the National Marine Fisheries Service, the State of Hawaii, and the U.S. Fish and Wildlife Service in the tripartite Northwestern Hawaiian Islands Investigation in the mid 1970's to early 1980's. This program increased knowledge of resource potential (Uchida and Uchiyama, 1986) and ultimately led to a geographic expansion of the lobster and bottomfish fisheries to the NWHI (Polovina, 1993; Haight et al., 1993), providing a marked expansion of exploitable biomass. Within the NWHI lobster fishery, changing gear from wire to plastic traps led to significant catch of slipper lobster, which had been essentially unexploited with wire traps. As these resources become fully exploited, however, the available habitat for further expansion of insular fisheries in Hawaii declined markedly.

The pelagic fisheries sector has seen the most dramatic fluctuation in Hawaii. Improvement of vessel technology increased the range of the local trolling and handline fleet while other factors led to the near-demise of the skipjack pole-and-line ("aku") fleet; with the closure of the only cannery on Oahu, recent aku catches are nearly an order of magnitude below the historical peak (Boggs and Kikkawa, 1993). A general trend away from "bulk fisheries" for pelagics (e.g. fishcake, canned tuna) and development of "quality," high price products (e.g. sashimi tuna, transshipped products) has enhanced the market value of Hawaii's pelagic fisheries (Pooley, 1993b). Even so, continuing improvements in technology have led to substantial expansion of the longline fishery and more directed targeting for bigeye tuna and broadbill swordfish fishery during the late 1980's (Boggs and Ito, 1993).

## Management Issues

With the decline of traditional management approaches, increasing population, and development of new fisheries, declines in nearshore stocks were inevitable (Shomura[1]; Hensley and Sherwood, 1993). As offshore fisheries grew, allocation conflicts have developed (Boggs and Ito, 1993). With the passage of the Magnuson Fishery Conservation and Management Act of 1976 (MFCMA) and establishment of the regional fishery management councils, federal jurisdiction was established and in some cases established regulations that superseded state or territory regulations. As the Western Pacific Regional Fishery Management Council (WPRFMC) began to develop fishery management plans (FMP's), the lack of adequate fisheries data became evident. Although time series of fisheries catch information were available in the state of Hawaii, questions existed about the quality and consistency of these data for rigorous analysis (Smith, 1993). Data for Hawaii's recreational fisheries, which may represent a large portion of harvest in the nearshore areas, are virtually unrecorded. In Guam, American Samoa, and CNMI, however, de novo development of the WPACFIN system began consistent time series of fisheries data (Hamm, 1993).

Management mechanisms have evolved in Hawaii to reduce fishing effort in the commercial fisheries, including limited entry (bottomfish, lobster), moratoria on new entrants to the fishery (longlining), closed seasons and quota (lobster), and area closures (longlining). Nearshore areas in Hawaii have received limited protection through Marine Life Conservation Districts (MLCD's), a progressive approach taken by the Division of Aquatic Resources (Smith, 1993). Such closed areas for fishery management purposes represent an alternative that is consistent with interest in marine refuges and sanctuaries, and a theoretical basis for such management is developing (DeMartini, 1993). Closed areas have also been used for special purposes, such as creating areas for nonconsumptive use of marine resources (a function served by many Hawaii MLCD's) or for protection of sensitive areas. An example of the latter is protection of the Hawaiian monk seal in the NWHI (Nitta and Henderson, 1993). Lobster fishing is prohibited inside 10 fm in the NWHI owing to designation of critical habitat for the monk seal, and longlining is prohibited within 50 n.mi. of the NWHI owing to fishery interactions.

Interactions among different scales of fisheries and the differing agencies responsible for their management present a challenge in many areas. In the nearshore, non-selective gears like gillnets and lack of data on their catch make specific management measures difficult and contribute to stock declines. Moving offshore, many stocks, such as bottomfish, fall within the jurisdiction of both state (or territory) and federal management prerogatives; this problem is presently being faced with bottomfish management in the main Hawaiian Islands. For pelagics, even though all species are now under the MFCMA, fluctuations in catch rates of many species mimic many of the changes in Pacific-wide stocks, suggesting that local fluctuations are in concert with the wider Pacific stocks, and that local effects often change with environmental variation. Unfortunately, the wider ranging stocks lack the scientific basis and institutional structures needed for management (see Doulman, 1987).

## Environmental Issues

Improved awareness of environmental issues in the marine environment is evident in the general public, and Hawaii and the Pacific islands are no exception. Land-based development associated with increasing population in island ecosystems is a serious concern owing to degradation of nearshore habitats (Boehlert et al.[2]; Baines and Morrison, 1990). Examples of problems include point and nonpoint source pollution, coastal landfills, diversion of freshwater from former estuarine areas or fishponds, dredging and siltation impacts on corals, and algal blooms. While such problems may not be evident in all these island areas, their relationship to human population pressure is well documented.

Fishing can itself impact the environment; destructive fishing practices (bleach, dynamite, or nonselective gears) have a long history in island areas, but public awareness has led to regulations banning or controlling them. Set gillnet fishing is increasingly viewed as a nonselective method with relatively high bycatch of unintended species, similar to driftnet fisheries. In Hawaii, however, bills to regulate set gillnets have routinely been killed politically, although a recent (1992) resolution calling for studies to improve regulations was passed.

Impacts of fishing on protected species is also a point of environmental concern. Examples in local fisheries include gillnet impacts on turtle, and longline takes of turtles, monk seal, and seabirds (Nitta and Henderson, 1993).

Fishing may also have impacts on biological diversity. Fishing only selected species in the high diversity ecosystems characterizing these areas may lead to species replacement, and the new dominant species may be smaller and less useful for human consumption (Jones, 1982). While concrete documentation of such species replacement is not evident in Hawaii and the U.S. insular Pacific fisheries, experimental fishing on patch reefs at Midway did change community structure and the abundance of certain prey species (Schroeder, 1989). A more dramatic example is provided by the trawl fishery in the Gulf of Thailand, where the dominant fish and large invertebrate species decreased to less than one-fifth of their original abundance (as reflected in catch rate), and the squid *Loligo* spp. became the clear dominant, with perhaps a ten-fold increase in abundance (Longhurst and Pauly, 1987). Multispecies management models for tropical fisheries are not sufficiently well developed to predict these kind of changes (Sainsbury, 1982).

## Concluding Remarks

The papers in this volume document the development of this region's fisheries and indicate the scope of research that has been conducted by many agencies; still, it is clear that much remains to be learned. This is also true for the fisheries management and environmental protection issues as for the basic biological and environmental research required to understand the physical processes at work in these diverse island habitats. For successful fisheries management, however, it is critical to appreciate the human diversity of these island areas; this requires a deeper understanding of the social processes which affect the ability of government to work with the community on common solutions to fishery management problems. I hope that this volume contributes the basic background information which can place the search for such solutions on a firmer scientific footing.

# ICHTHYOPLANKTON ASSEMBLAGES AT SEAMOUNTS AND OCEANIC ISLANDS

*G. W. Boehlert and B. C. Mundy*

## ABSTRACT

Seamounts and oceanic islands support demersal or neritic fish populations and are localized sources of eggs and larvae added to a background of oceanic ichthyoplankton. Associated larval fish assemblages, however, have been identified in few studies, and most have been based on subjective classifications of species by reproductive characteristics. At seamounts, little evidence exists that ichthyoplankton assemblages differ from the background field despite physical mechanisms proposed to maintain planktonic forms. Larvae of bottom-associated species are notably rare in samples taken in these regions. In contrast, characteristic ichthyoplankton assemblages have been described at oceanic islands. Unique assemblages may exist in embayments and lagoons, but they are not well described. Nearshore assemblages (0 to 0.5 km offshore) are dominated by larvae of small species with demersal eggs; neritic assemblages (0.5 to 5 km offshore) include inshore species with demersal and planktonic eggs mixed with larvae of certain species that are usually oceanic as adults. Although larvae of some inshore species with pelagic eggs are found offshore in oceanic assemblages (beyond 3 to 5 km), assemblages there are poorly described. Spatial and seasonal spawning behavior of adults plays the key role in formation of ichthyoplankton assemblages. Mechanisms that may maintain ichthyoplankton assemblages at islands include boundary layers, small scale frontal dynamics, tidal currents, topographically produced eddies, seasonally reduced or variable currents, and regions of no or returning flow. Behavior of larvae, particularly that affecting vertical distribution, can modify the influences of these mechanisms. The integrity of assemblages can be disrupted by both biotic and abiotic factors.

Seamounts and isolated oceanic islands are habitats for demersal and pelagic fish communities not found in the open ocean. These communities are point sources of eggs and larvae that contribute to ichthyoplankton assemblages of the surrounding oceanic waters. Recruitment back to seamounts and islands depends upon the fate of the egg and larval stages and thus, to some extent, upon their retention near these habitats. Distance from these isolated habitats is therefore an important variable in consideration of such assemblages.

The unique problem that seamounts and oceanic islands pose to the recruitment of fishes was first stated by Gosline and Brock (1960): ". . . the possibility presents itself that variations in the normal pattern of oceanic currents around the islands may sweep a variable number of these young fish with their relatively feeble swimming abilities beyond the point of no return." They also suggested, "This argues that the migratory pattern of these fishes is uniquely adapted to best assure their return to the inshore habitat at the proper time." Their suggestions have since formed the basis of the hypotheses investigated by most studies of ichthyoplankton in island areas.

The factors affecting the existence of ichthyoplankton assemblages may be conveniently classified into those influencing formation, maintenance, or disruption (Table 1). The formation of assemblages is influenced not only by adult spawning patterns, but also by current-topography interactions that may accumulate buoyant plankton (Miller, 1974; Wolanski et al., 1989; Black and Moran 1991). Optimal physical and biotic conditions may also lead to species associations (e.g., "ecological safe sites"; Frank and Leggett, 1983). Maintenance of larval fish assemblages involves an increasing role of larval fish behavior, including seeking specific environmental features (Sulkin, 1986; Olla and Davis, 1990), and prey-

Table 1. Factors of potential importance in the formation, maintenance, and disruption of ichthyoplankton assemblages around islands and seamounts

| Type of factor | Influencing formation* | Influencing maintenance† | Influencing disruption‡ |
|---|---|---|---|
| Adult behavior | Spawning location<br>Spawning time (tidal, diel, lunar, seasonal) | None | Predation (cannibalism)<br>Influences on settlement |
| Egg development | Buoyancy (demersal vs. pelagic eggs, egg density)<br>Incubation time<br>Hatching location<br>Hatching time | None | None |
| Larval behavior | Buoyancy at hatching<br>Swimming ability at hatching | Habitat preference (temperature, salinity, light, depth)<br>Vertical migration | Ontogenetic changes in vertical distribution<br>Metamorphosis (settlement, schooling) |
| Biotic environment | Predation (absence will create "ecological safe sites") | Prey presence | Predation<br>Prey absence (starvation) |
| Abiotic environment | Convergences<br>Fronts | Eddies (Taylor Columns)<br>Upwelling<br>Downwelling<br>Internal waves<br>Convergences<br>Fronts | Diffusion<br>Mixing<br>Advection |

* Factors promoting spatial and temporal co-occurrence.
† Factors promoting integrity of assemblages over time.
‡ Factors causing eventual breakdown of assemblage structure.

searching behavior (Hunter and Thomas, 1974; Doherty et al., 1985). Behavioral interaction with hydrography may result in dramatic accumulations of larvae into very localized assemblages (Kingsford, 1990). Because islands and seamounts may also be the loci of enhanced primary productivity (Doty and Oguri, 1956; Genin and Boehlert, 1985), retention near these areas may confer an advantage in survival.

In opposition to the factors forming and maintaining ichthyoplankton assemblages are those disrupting them. Mixing from turbulent flow, wind events, or other features will disrupt assemblages and dilute them over time. Advection may retain an assemblage intact, but can alter its position relative to a fixed sampling point, and thus its detection. Changes in larval behavior with ontogeny may alter the assemblage composition over time. Finally, the end of participation in an assemblage may be considered the point at which juveniles leave the environment occupied by larvae.

Investigations of ichthyoplankton assemblages at oceanic islands are still at the stage of describing general patterns (Boehlert et al., 1992; Leis, 1991), and those at seamounts are even less detailed. In this paper, we review the available information on 1) ichthyoplankton distributions at isolated seamounts and oceanic islands as they relate to spatial assemblages, 2) evidence that larvae of topographically associated species are maintained locally, and 3) the physical and biological mechanisms that may form, maintain, or disrupt assemblages near each type of topographic feature.

## SEAMOUNTS

*Physical Mechanisms.*—Local recruitment by retention of larvae above a seamount is an attractive hypothesis, but one not easily visualized in the face of diffusive and advective forces. Potential mechanisms retaining larvae must be characterized by specific time and space scales. The time scales most pertinent to the formation and maintenance of larval fish assemblages are on the order of weeks to months, involving spawning and egg and larval development. We consider two spatial scales pertinent to larval assemblages: the near-field area around small seamounts (<ca. 10 km summit diameter) and the far-field area surrounding seamount chains, very large banks, or seamount complexes.

Current-topography interactions on both scales at seamounts have received a great deal of attention from physical oceanographers. Perhaps most interesting is the generation of semi-stationary eddies (Taylor columns) above seamounts. Other oceanographic complexities are present at seamounts, however, including internal wave reflection (Eriksen, 1982), tidally induced currents and eddies (Meincke, 1971), trapped waves (Brink, 1989), and eddies shed downstream (Royer, 1978). To examine their potential role in maintenance of biological populations, one must consider the speed and temporal variability of impinging currents, the temporal stability of topographic effects, and the size and shape of the seamount of interest.

Taylor columns are characterized as closed-streamline anticyclonic vortices above topographic obstacles in an impinging flow (Fig. 1A). They have been predicted theoretically, demonstrated experimentally in the laboratory (Taylor, 1917; Huppert and Bryan, 1976), and observed in the field (Owens and Hogg, 1980; Dooley, 1984). They can extend from the seamount summit to the ocean surface or, in the case of a stratified ocean, to the bottom of the pycnocline (Bakun, 1988). Development of Taylor columns frequently involves upwelling along the seamount flanks (Bezrukov and Natarov, 1976). Shomura and Barkley (1980) first speculated that Taylor columns may maintain planktonic stages and facilitate recruitment, and suggested that differences in the biota and productivity among seamounts might be attributed to variability in the occurrence and intensity of Taylor columns. For small seamounts, the temporal persistence of trapped vortices is a key question. Development of a Taylor column is based upon seamount morphology, current speed, water column stratification, and the Coriolis parameter. At a given seamount, temporal variations in the impinging current flow (including tidal factors and other time-variant flows) and stratification are the causes of temporal variations in vortex development. Decreased current speeds can result in the breakdown of the vortex, whereas excessive speeds can result in eddies being shed downstream (Hogg, 1980). Under certain circumstances, tidal currents may generate similar vortices above seamounts; Meincke (1971) observed an anticyclonic vortex trapped above Meteor Seamount, and concluded that it was driven by tidal influences.

The persistence of Taylor columns relative to biological time scales is poorly known. Existing evidence at smaller seamounts does not support physical time scales that match the requisite biological time scales. Genin and Boehlert (1985) noted uplifted isotherms and higher chlorophyll levels over a small seamount and suggested the presence of a Taylor column with a likely residence time of a few days; it was not present 2 and 17 days later. Darnitsky et al. (1984) observed upwelling only twice over Wanganella Bank during six cruises in 4 years. Although longer periods of Taylor-column persistence (on the order of several months) were inferred from hydrographic and Eulerian current measurements above a deep

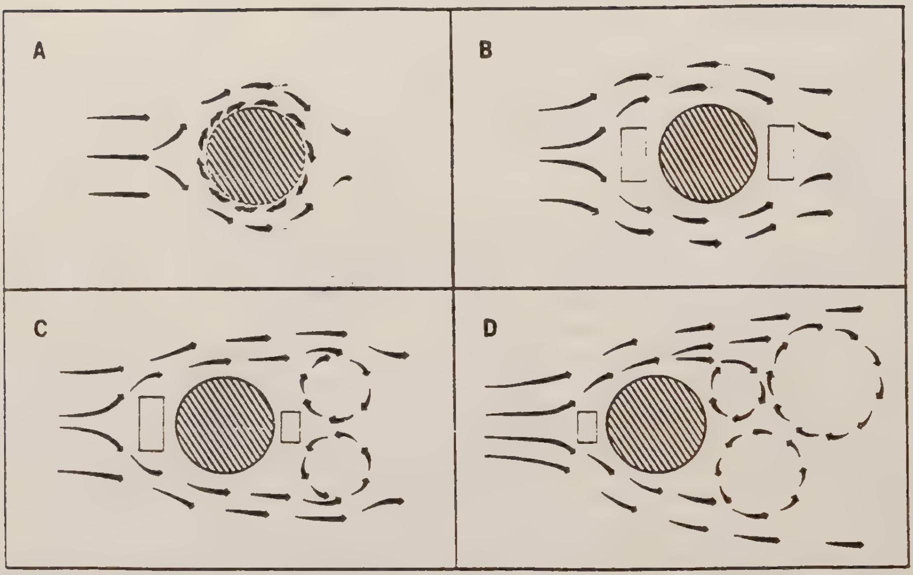

Figure 1. Variations in current-topography interactions. A. Interaction of flow with a seamount may lead to an eddy-like Taylor column remaining stationary over the summit (after Hogg, 1980). B–D. Interactions of a cylindrical island in a unidirectional current flow (after Hamner and Hauri, 1981). Slow current speeds result in laminar flow (B); increasing current leads to turbulent flow with downstream, contra-rotating eddies (C). Further increases lead to eddy shedding downstream (D). Stippled areas indicate stagnation points in the flow.

seamount in the North Atlantic (Owens and Hogg, 1980), the area was characterized by steady flow not commonly observed at shallow (<200 m) depths where most fish larvae occur.

At greater spatial scales (beyond the immediate area of the seamount summit), however, time scales may be appropriate for formation and maintenance of ichthyoplankton assemblages. Anticyclonic eddies shed from seamounts or seamount chains may remain in the general vicinity, as shown by Lagrangian current observations from satellite-tracked drifters (Cheney et al., 1980); retention of ichthyoplankton in the general region of seamounts may occur within such eddies for periods up to several weeks. These eddies can cause physical and biological variability in downstream waters (Royer, 1978; Genin et al., 1988), but detection of a biological signal (or larval fish assemblage) attributable to a seamount effect would require detailed biological and physical sampling as well as knowledge of the history of the water parcel.

At very large banks, some observations support the presence of quasi-stagnant water masses that may retain larvae. Eide (1979) observed this over a bank off the coast of Norway and found it consistent with the Taylor-column theory. Similar suggestions have been proposed for Rockall Bank, where Dooley (1984) noted episodic breakdowns of the gyral structure and suggested that these could have effects on variability in year-class strength of commercial fishes because of inconsistency in larval fish retention. Loder et al. (1988) characterized the oceanography at four large banks in the northwestern Atlantic, all of which have residual circulation indicative of anticyclonic motions around the bank. By considering the overall physical oceanography in light of time and space scales of water exchange in the around-bank, cross-bank, and vertical directions, they reduced highly complex flow patterns to more understandable terms relative to biological time and space scales. Of the four banks, only Georges Bank appeared to have water residence times approximately equal to or greater than the recirculation time of the gyre; it was thus the best candidate for consistent retention of larval stages and possibly assemblages.

*Seamount Ichthyoplankton.*—The first study of ichthyoplankton at a seamount was at the Great Meteor Seamount off North Africa in 1970 (Nellen, 1973, 1974). This seamount was not deemed to be conducive to the spawning and early survival of fishes but instead acted as a disturbance to the surrounding pelagic ecosystem. Larvae of oceanic species were reduced in numbers and diversity over the seamount summit. Nellen (1973, 1974) suggested that predation or physical damage during diel descent to the seamount plateau increased the mortality of vertically migrating oceanic species. In contrast, larvae of two topographically associated species were more abundant at the summit than in the surrounding ocean. From this, he suggested that non-migrating larvae of species spawning over the seamount were maintained by currents. Larvae of euneustonic species were neither more abundant nor subject to increased mortality at the seamount. Nellen (1973) suggested two influential hypotheses: hydrography may maintain larvae of species spawning over seamount summits; and predation and exclusion of migrators reduce the abundance of oceanic larvae over seamounts.

These hypotheses are neither entirely supported nor refuted by other studies. Later sampling at the Great Meteor Seamount failed to find concentrations of topographically associated species (Belyanina, 1984). No evidence of retention of larvae was found at seamounts in the Indian Ocean (Belyanina, 1985). Conflicting results were obtained from samples taken within and between seasons at a seamount in the central North Pacific Ocean (Boehlert and Genin, 1987; Boehlert, 1988). In summer, larval fish densities were not different above and away from the summit during the day in three of the four depth strata sampled, but were more abundant away from the summit at all depths at night. In winter, larvae were more abundant over the summit than away from it at all depths during day and night (Boehlert and Genin, 1987). Boehlert (1988) suggested an interaction of three factors to explain the biological observations: first, semi-stationary eddies could maintain larval fish populations over the summit; second, vertically migrating taxa would be excluded from the summit's region by its physical presence; and third, predation at the summit would reduce the abundance of oceanic taxa. He concluded that none of the factors alone could explain the observations, but their interaction probably increased biological variability in the ocean above and downstream from the seamount.

There have been no studies explicitly identifying ichthyoplankton assemblages at seamounts. Three generalities about groups of fish larvae found at seamounts may be extracted from published studies: 1) the dominant larvae at most seamounts are widespread oceanic species (typically oceanic species of the Myctophidae and the Stomiiformes); 2) larvae of topographically associated species are rare at all but shallow seamounts; and 3) the abundance of larvae of topographically associated species often decreases with increasing distance of seamounts from larger land masses.

Surprisingly few studies have found larvae of topographically associated species to be more abundant at seamounts than in the surrounding ocean. Larvae of benthic species were found to be dominant in only one study (Robertson and Mito, 1979), a gadiform, *Gaidropsarus novaezealandiae*, and a bovichtid, *Bovich-*

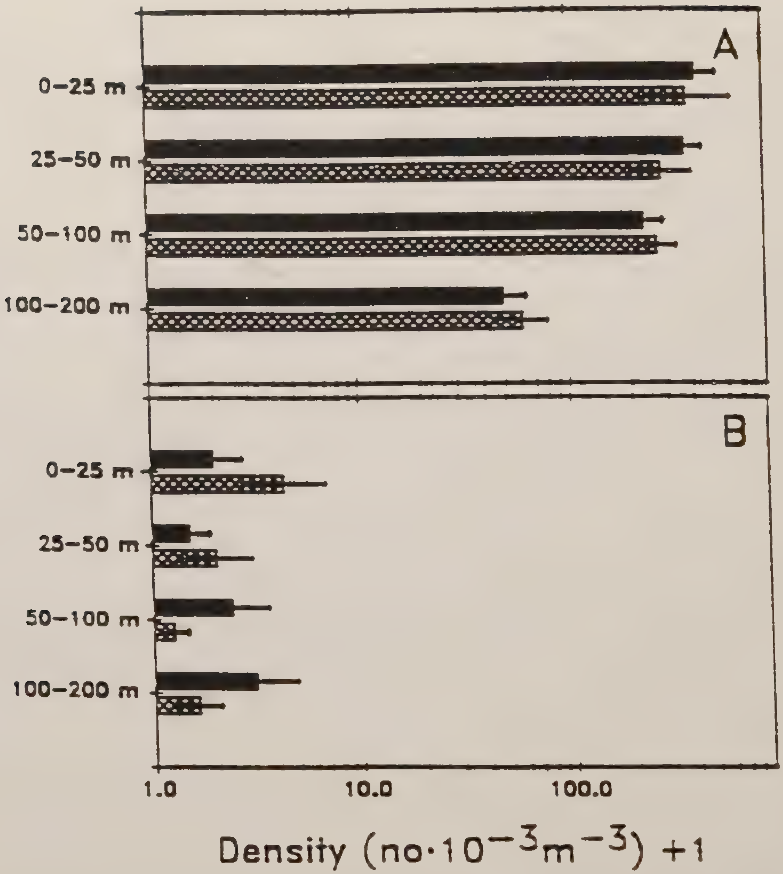

Figure 2. Densities of oceanic larvae (A) and seamount-associated (demersal or benthopelagic) larvae (B) at Southeast Hancock Seamount in July 1984 (summer) and February 1985 (winter) with replicate samples during day and night at four discrete depths (from Boehlert and Mundy, unpubl.). Solid bars indicate densities over the seamount summit; cross-hatched bars indicate densities at a station 20 km west of the summit. Error bars indicate ±1 SE.

*tus variegatus*, at banks off New Zealand. Larvae of seamount-associated species were notably rare in studies at the Hancock Seamount in the central North Pacific Ocean (Boehlert, 1988). On average, they were at least one hundred times less abundant than oceanic species (Fig. 2). The rarity of larvae of topographically associated species at this seamount is unexpected, because it supports large populations of demersal fishes (Sasaki, 1986).

Detailed examination of the distribution of larvae at Southeast Hancock Seamount provides further evidence that larvae of most species were not retained over the seamount summit. Sampling consisted of two cruises (July 1984 and February 1985) with stations above and 20 km to the west of the seamount summit in each cruise; samples at both stations were taken in four discrete depth strata (Boehlert and Genin, 1987; Boehlert, 1988; Fig. 2). Additional samples were taken in the neuston (0 to 1 m) in winter. Seamount taxa at 0 to 50 m were most abundant away from the seamount (Fig. 2). The dominant species in these strata was *Beryx splendens*, collected only in summer (Mundy, 1990). Only in the two deepest strata (50 to 200 m) were larvae of seamount taxa more abundant over the seamount summit than away from it (Fig. 2). These were almost all *Maurolicus muelleri*, which were collected only in winter (Boehlert and Mundy, unpubl.). Larvae and small juveniles of *Pseudopentaceros wheeleri*, the dominant species in samples of adult fishes at this seamount, were only collected in neuston tows. Dispersal of *P. wheeleri* away from seamounts may actually be enhanced by the exclusive occurrence of their larvae in the neuston (Boehlert and Sasaki, 1988), where wind-driven advection will rapidly disperse the larvae away from their source. Thus, evidence exists for greater abundance of larvae of only one species, *M. muelleri*, over Southeast Hancock Seamount. Demonstrating retention of larvae at the seamount, however, will require more detailed information on ocean currents and the distribution of late larval stages.

The frequency of occurrence and abundance of larvae of topographically associated species decrease with increasing distance of seamounts from larger land masses and increasing summit depth. Nellen (1973, 1974) suggested that although the neritic species with abundant larvae were spawning at the Great Meteor Seamount, reproduction there was unlikely to sustain populations. Such "dependent populations" have also been noted at seamounts in the central North Pacific (Belyayev, 1990). In the Indian Ocean, larvae of shallow water fishes were absent from two seamounts isolated from continental areas and present at two seamounts closer to shelf areas (Belyanina, 1985). A similar pattern was found in a more intensive study of one deep (182 m) and three shallow (10 m) seamounts in the same region (Gordina and Bladimirtsev, 1987). In the latter study, larvae of neritic species were most abundant at shallow seamounts.

Several sampling problems are apparent with existing surveys of ichthyoplankton around small seamounts. First, temporal sampling patterns have been inadequate to detect seasonal peaks of larval abundance for certain species. Second, spatial sampling in the studies identified above is typically restricted to stations above the summit and at some distance away from the summit. Thus, analysis of the spatial distributions of larvae was often based upon paired comparisons, as opposed to a broader geographic analysis and consideration of variables such as current direction. A related problem is that almost no studies have reported measurements of currents simultaneous with ichthyoplankton collections. Gordina and Bladimirtsev (1987) found that larvae of neritic species were concentrated in eddies downstream of shallow (10 m) seamounts, rather than directly above the summit centers. Oceanic larvae dominated in upstream areas. The distribution of neritic larvae was given as evidence that such larvae may be advected from their source but retained in the vicinity of shallow seamounts by eddies.

The problems of spatial sampling and oceanographic measurements have been better addressed at certain large banks. Rockall Bank (Dooley, 1984), Georges Bank (Smith and Morse, 1985), and Browns Bank (Campana et al., 1989) show characteristic eddies that have been proposed to maintain eggs and larvae through the planktonic stages to promote local recruitment. Even so, Campana et al. (1989) suggested, the Browns Bank mechanism was a "leaky gyre," and cohorts of larval haddock, *Melanogrammus aeglefinis*, were split into retained and vagrant groups. Above some threshold size, banks may have self-sustaining populations, but typically with species characteristic of adjacent continental shelves or slopes. The processes described in Loder et al. (1988) seem to be applicable in such cases.

To summarize, seamount ichthyoplankton assemblages containing topographically associated species have been most frequently identified near shallow (<200

m) summits which are near larger land masses. There is little evidence that persistent ichthyoplankton assemblages, distinct from those in the surrounding ocean, exist near deeper, more isolated seamounts. The physical interference of seamounts with vertical migration and the high predation rates at seamount flanks and summits generally act to increase variability in plankton at seamounts and downstream therefrom (Genin et al., 1988). Thus, fish that spawn at seamounts may be subject to extreme variability in recruitment due to dispersal of larvae away from adult habitats. Recruitment to seamounts may depend more upon occasional events than it does at oceanic islands. Recruitment of many species at seamounts may also include major input from populations at larger land masses (Nellen, 1973; Vasilenko and Sokolovskaya, 1989). The combination of highly variable and occasionally allochthonous recruitment may help explain several features of fish populations at seamounts, including the lower than expected rate of endemism (Wilson and Kaufman, 1987), susceptibility of seamount populations to recruitment overfishing (Sasaki, 1986), and unpredictable recovery after overfishing (Lutjeharms and Heydorn, 1981).

## OCEANIC ISLANDS

An early hypothesis about the distribution of larval fishes at oceanic islands suggested that larval Acanthuridae might be retained in their vicinity by small eddy systems (Randall, 1961). Sale (1970) found larval acanthurids to be more abundant offshore (48 to 58 km) than near Oahu, Hawaii (4.8 to 8.0 km), and also proposed that eddies returned these larvae to the island. These suggestions have been generalized to other families of fishes (Johannes, 1978). Prior to the publications of Miller (1974) and Watson and Leis (1974), however, there was almost no empirical information on the distribution of ichthyoplankton near oceanic islands to allow informed speculation about these ideas.

Early surveys off Oahu suggested that fish larvae were not distributed near islands as if they had passively diffused from the island source (Miller, 1974). Distinct differences in the distributions of taxa indicated the influence of behavioral differences (Watson and Leis, 1974). Larvae of certain highly visible reef families, including the Acanthuridae, Chaetodontidae, Labridae, and Scaridae, were rare in nearshore samples (Miller, 1974; Leis, 1978). The early suggestion that some types of larvae occur far from shore (Sale, 1970) has been verified. Larvae of labrids and pomacentrids, for example, have been found 370 to 1200 km from the nearest adult habitat (Leis, 1983; Victor, 1987). The occasional occurrence of such larvae at extreme distances does not mean that they are most abundant away from land; several taxa often considered to have widely dispersed larvae are actually most abundant at intermediate distances from shore (Wyatt, 1982; Young et al., 1986; Leis, 1989; Clarke, 1991).

The planktonic habitat near oceanic islands is occupied preferentially not only by larvae of topographically associated fishes, but also by larvae of certain oceanic fishes (Miller, 1979; Leis et al., 1991). The importance of this habitat to these oceanic species is unknown. As an example, the increased nearshore abundance of tuna larvae in the genus *Thunnus* (Fig. 3) may simply be a result of the higher abundance of spawning adults near islands. Tunas typically aggregate near islands and banks for feeding (Uda and Ishino, 1958), but larvae are not regularly concentrated in other areas of adult occurrence, such as fronts. An alternate hypothesis is that waters around islands are more suitable for survival of early larvae, perhaps through improved feeding conditions. Primary productivity around islands, may be higher than in the open ocean (the "island mass" effect), particularly around

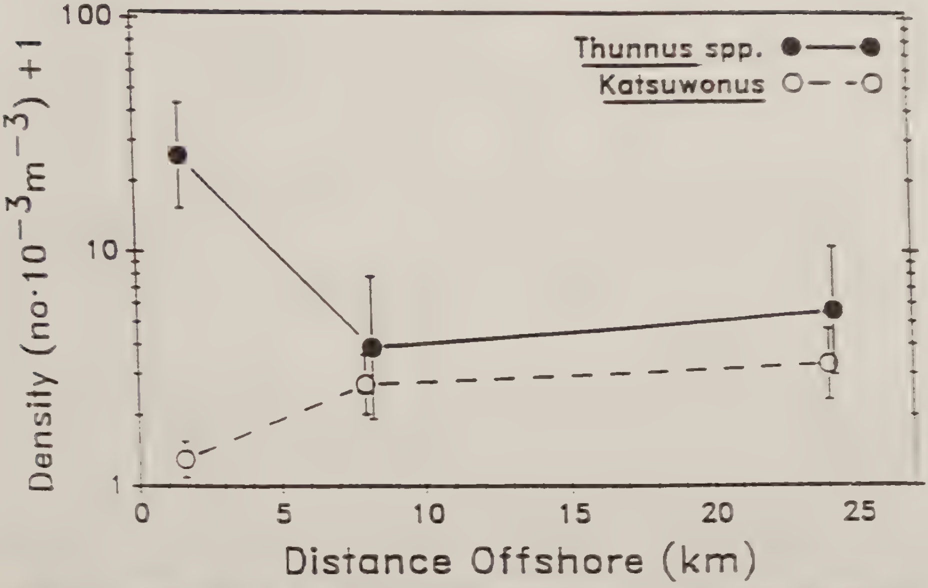

Figure 3. Onshore-offshore patterns of distribution of *Thunnus* spp. and *Katsuwonus pelamis* collected during June 1986 off the leeward coast of Oahu, Hawaii. Values are means from discrete-depth samples taken in the upper 40 m for *Thunnus* spp. (N = 10 nearshore station, N = 6 at each offshore station) and the upper 80 m for *K. pelamis* (N = 16 nearshore station, N = 10 at each offshore station). Error bars indicate ±1 SE.

high islands, such as Oahu (Gilmartin and Revelante, 1974; Dandonneau and Charpy, 1985). Waters near islands in tropical and subtropical areas may also be characterized by increased zooplankton abundance, often of species uncommon in offshore waters (Jones, 1962; Hernandez-Leon, 1988, 1991). Thus, greater availability of prey in nearshore waters could result in higher survival rates for early larvae during the stage when prey density requirements are highest (Hunter and Kimbrell, 1980). In the case of *Thunnus* spp., Higgins (1970) noted a threefold higher abundance of juveniles at stations 56 km, as opposed to 7 km, offshore of Oahu. Such oceanic larvae may thus disperse from nearshore areas with increasing age as their prey-searching capabilities improve. The case is made, however, for possible enhanced survival for larvae developing in waters around islands.

*Sampling Problems.*—Description of the distributions of larvae of many island-associated fishes has been hampered by their low abundance in the plankton. Larvae of one of the most visible coral reef families, the Chaetodontidae, comprise <0.5% of the total larvae in ichthyoplankton surveys (Leis, 1989). Clarke (1991) noted that the average densities of many taxa 13 km off Oahu, including those previously described as rare inshore, typically range from 0.0001 to 0.01·1,000 $m^{-3}$. He pointed out that it is necessary to sample water volumes >1,000 $m^3$ to describe the distributions of most island-associated species. This has not been done in most studies. The sampling problems of accurately describing the distributions of naturally sparse fish larvae enhance the utility of examining larval fish assemblages. Patterns may be detected in assemblages that are obscured by the patchy distribution or low sample sizes of individual taxa.

Spatial and temporal scales of sampling have often been insufficient to identify the spatial extent or temporal persistence of assemblages. The time and space scales pertinent to larval fish assemblages around islands vary with island size but are ill-defined for virtually all islands. The biological time scales are on the order of weeks to months, the characteristic time scale for the pelagic period prior to recruitment to the juvenile or adult habitat (Thresher and Brothers, 1989). Spatial scales of biological interest are dependent upon the habitat type used by the species of fish (demersal or pelagic), the spawning type (pelagic or demersal egg), and perhaps the distances characterizing diffusive and advective processes over the relevant time scale. Most studies of island ichthyoplankton have conducted onshore-offshore transects to analyze patterns of larval fish distribution. Because spatial sampling has largely ignored the larger scale of distribution around islands, spatial variation in assemblage distribution is poorly known. Thus, discussion of physical mechanisms relative to larval fish distribution around islands has been largely speculative.

*Early Evidence for Assemblages in Island Systems.*—The first suggestions that different assemblages of larvae exist at oceanic islands came from studies off Oahu. Miller (1974) noted that fish larvae were more concentrated in nearshore (<10 m depth) than offshore (>10 m depth) areas, larvae of certain offshore species were abundant inshore, and the abundance of larvae from demersal eggs was inversely correlated with the abundance of larvae of mesopelagic species. Watson and Leis (1974) found that larvae of pelagic bay species with pelagic eggs and reef species with demersal eggs were abundant within an embayment on Oahu. Larvae of oceanic species and reef species with pelagic eggs were rare in the bay; Watson and Leis (1974) suggested that these larvae completed their planktonic life in offshore waters. From this series of studies, Leis and Miller (1976) concluded that larvae of insular species from demersal eggs occur more frequently in a nearshore assemblage, while those from pelagic eggs are more frequent offshore.

The assemblages identified at Oahu form the basis for almost all subsequent work around islands. Evidence for at least four larval fish assemblages can be found in studies of ichthyoplankton distributions around islands subsequent to Leis and Miller's (1976) work: 1) assemblages unique to embayments and lagoons, 2) extreme nearshore assemblages, 3) intermediate nearshore assemblages, and 4) offshore assemblages. The latter three will be referred to as the "nearshore," "neritic," and "oceanic" assemblages, following Leis (1978).

*Embayment Assemblages.*—The presence of distinct assemblages in embayments and lagoons of oceanic islands (referred to as "embayment assemblages," for brevity) has not been investigated in detail. Although Leis (1981) did not observe a nursery function in a small reef lagoon within the Great Barrier Reef, larger lagoons and embayments on certain oceanic islands may differ in this respect. Preliminary results of studies at oceanic atolls in the Coral Sea (Leis, 1986a) and at French Polynesia (Leis, 1991) suggest that larval fish assemblages there consist of species not found in abundance outside of lagoons. The Gobiidae, Apogonidae, Pomacentridae, and Blenniidae are the dominant families in these assemblages. The initial suggestion that an embayment at Oahu had a unique assemblage of larvae (Watson and Leis, 1974) was corroborated by Leis and Miller (1976), Miller et al. (1979), and Kobayashi (1989; Table 2).

Recent collections within the lagoon of Palmyra Atoll, Line Islands, contained mostly larvae that were not found in samples outside of the reef, including many samples taken within 0.5 km of the atoll (Boehlert and Mundy, unpubl.). These lagoonal collections were also composed almost entirely of larval Gobiidae, Apogonidae, Pomacentridae, and Blenniidae. Thus, larval fish assemblages in enclosed

Table 2. Selected taxa included in larval fish assemblages proposed in studies at tropical and subtropical islands. The assemblages are those found in embayments (estuaries, lagoons, and other semi-enclosed areas), nearshore waters (0 to 0.5 km offshore), neritic waters (0.5 to 3–5 km offshore), and oceanic waters (3–5 to 600 km offshore). Egg types are noted because some assemblages were suggested to be dominated by larvae from either pelagic or demersal (including brooded or viviparous) eggs. Ubiquitous pelagic species are excluded because they form the background field of larvae to which island taxa are added

waters of oceanic islands may be qualitatively very different from those in enclosed lagoons of continental islands and tropical coasts (Table 2).

*Nearshore Assemblages.*—There is increasing evidence that some fish species have larvae found primarily at distances of 0 to 500 m from substrates (Barnett et al., 1984; Powles et al., 1984; Marliave, 1986; Jahn and Lavenberg, 1986). Leis (1978) described the assemblage at 200 m off leeward Oahu (Table 2). In a discussion of fish larvae at the Great Barrier Reef, which is not an island environment, Leis (1986a) noted that tripterygiids were among a special assemblage of larvae that could be frequently found ". . . in waters immediately to windward of coral reefs . . ." but which were ". . . found in high numbers nowhere else." This pattern was also found in a study at Palmyra Atoll, where the dominant larvae in samples collected <500 m from shore were tripterygiids, bythitids, gobiesocids, and certain gobiids, with this assemblage particularly abundant in a restricted portion of the island's circumference (Boehlert and Mundy, unpubl.). A comparison of larval densities north and south of the island in samples taken along the 100-m isobath, for example, shows dramatic differences (Fig. 4), with the greatest abundance on

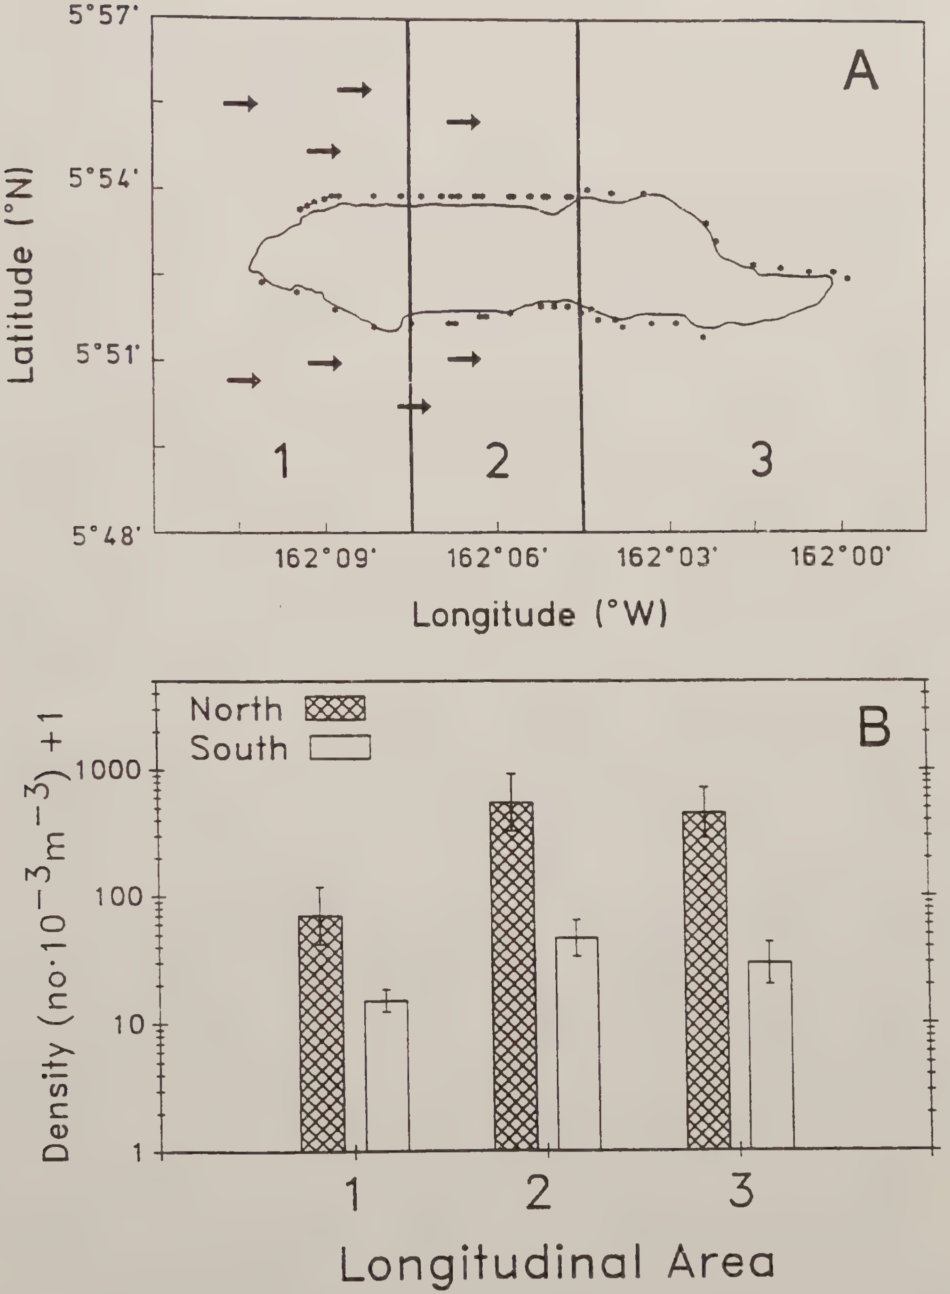

Figure 4. Larval fish distributions surrounding Palmyra Atoll in the central equatorial Pacific (Boehlert and Mundy, unpubl.). A. Outline of the 10-m isobath surrounding the island, with the sampling stations indicated by asterisks. All samples were taken during daylight hours with a 1-m² MOCNESS in the upper 50 m. Data are divided into three longitudinal strata. General current direction is indicated by arrows. B. Mean larval fish densities by longitudinal stratum, divided to north and south sides of the island.

the northern side of the island. Thus, although the taxonomic composition of nearshore assemblages varies between studies, there is increasing evidence that such assemblages predictably occur near islands.

Within the nearshore assemblage, other types of larvae may have even more restricted distributions (Table 2). Larvae of the clupeid genus *Jenkinsia* (Powles, 1977) and of the sciaenid *Pareques iwamotoi* (Powles and Burgess, 1978; Miller and Woods, 1988) were found extremely close to the bottom (<2 m) near coral heads. In the Virgin Islands, Caribbean Sea, larvae that were rare in towed net samples were taken near reefs and at the lights of an undersea habitat (Smith et al., 1987). In Kaneohe Bay, Oahu, Hawaii, larvae of two gobiid species also were found to be most abundant within a few meters of coral reef heads (Kobayashi, 1989). These may be tropical, insular examples of larvae that are restricted in distribution to within a few meters of a substrate (Marliave, 1986). This near bottom habitat is sorely undersampled in island waters, as elsewhere.

*Neritic Assemblage.* —Most studies of larval fish distributions around islands have found evidence for an assemblage of larvae distributed in a band of approximately 0.5 to about 3 to 5 km from shore, but these distances may vary around different parts of islands, depending upon current strength and island morphology. The neritic assemblage is typically dominated by insular taxa with demersal eggs and a few oceanic taxa (Table 2). The contribution of insular taxa with planktonic eggs to this assemblage is not yet resolved, with more investigation being clearly required (Clarke, 1991). Components of the neritic assemblage off leeward Oahu vary between studies because of different analysis techniques. Leis (1978, 1982) identified an assemblage from an analysis of absolute abundances, while Leis and Miller (1976) used relative densities of larvae. Miller et al. (1979) combined the nearshore and neritic assemblages in their analysis.

A neritic assemblage similar to that off Oahu was found close to the lee of Johnston Island, an isolated atoll several hundred kilometers southwest of Hawaii (Boehlert et al., 1992). That study sampled a grid around the island on a scale pertinent to the neritic assemblage. An assemblage consisting of three groups of strictly island-related species was noted (Table 3). Two of the groups were small, with two and three taxa that were fairly rare but most abundant in the 50- to 100-m depth stratum. The largest group was composed of highly abundant taxa present in areas beyond the neritic area and throughout the upper 200 m but clearly most abundant in neritic waters in the 50- to 100-m stratum (Boehlert et al., 1992). The scale of the areas of high abundance for this assemblage relative to the island, however, was markedly greater than the distances normally seen in neritic assemblages and encompassed distances of ≤10 km downstream of the island, whereas the assemblage was rare upstream of the island, as would be expected (Fig. 5A). Similar upstream/downstream differences in larval fish abundance were noted at this scale at Jamaica (Wyatt, 1982).

The oceanic species found in neritic larval fish assemblages include three components: species associated with topography as adults, within families usually considered mesopelagic; widely distributed species with larvae abundant in all regions; and those with larvae concentrated in neritic regions. Examples of topographically associated species with larvae found in the neritic assemblage include *Lampadena urophaos* (Leis, 1978) and *Benthosema fibulatum* (Boehlert and Mundy, unpubl.) off Oahu, and *Scopelosaurus gibbsi* off Muraroa (Bourret et al., 1979). Widely distributed species with widely distributed larvae include *Ceratoscopelus warmingi* (Leis, 1978). A group of ubiquitous larvae that acted as a background field contributing to neritic and oceanic assemblages at Johnston Atoll included nine species that were present in over 66% of all samples (Table 3).

Table 3. Larval assemblages identified from an ichthyoplankton survey surrounding Johnston Island in the central tropical Pacific Ocean. Depths sampled included 0–50 m, 50–100 m, and 100–200 m. The species groups within assemblages were determined with a two-way synthesis table technique. Several other abundant species were not characterized by distributions coherent with other groups (from Boehlert et al., 1992)

These were not included in the assemblage analysis by Boehlert et al. (1992). Three of five assemblages of rarer oceanic taxa were less abundant in the neritic region, suggesting the possibility of exclusion from neritic waters, whereas two others were ubiquitous across areas. Examples of widely distributed taxa with larvae concentrated in neritic areas include *Thunnus albacares* (Fig. 3; Miller, 1979; Leis et al., 1991; Boehlert and Mundy, 1991) and the Istiophoridae (Leis et al., 1987).

*Oceanic Assemblage.*—The inshore limit of the oceanic assemblage around islands is found 2 to 5 km offshore; the seaward limit of this assemblage is poorly known (Leis and Miller, 1976). Note that "oceanic" in this context does not refer to an assemblage consisting only of larvae of oceanic species; rather, it refers to the assemblage containing larvae of insular taxa found at the greatest distance from an island in oceanic waters (Table 2).

The inshore distance for the transition between oceanic and neritic assemblages is most probably an artifact of sampling effort; identification of the true distance and its variability will depend upon continuous sampling in offshore transects covering different regions of an island. The offshore extent of oceanic assemblages is unknown largely because of limited sampling. Larvae of island-associated taxa have been found at great distances from the nearest adult habitat (Leis, 1983;

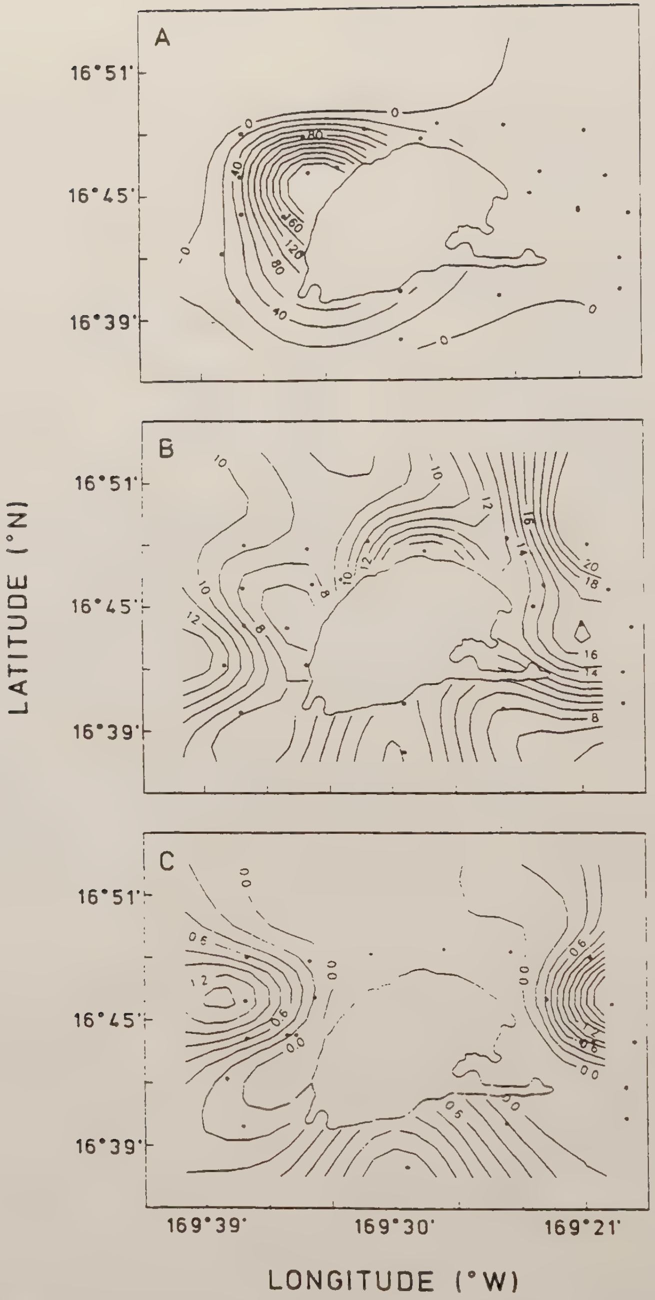

Figure 5. Distribution of ichthyoplankton around Johnston Island: the outline surrounding the island represents the 18-m isobath (data from Boehlert et al., 1992). General current flow in the region is from east to west with a moderately stagnant area downstream of the island where the highest densities in 5A occur. All density notations are in larvae per 1,000 m$^3$. 5A. Distribution of the combined densities of species included in the first neritic assemblage (Table 3: assemblage A, dominated by *Eviota epiphanes*) in the 50 to 100 m depth stratum. 5B. Distribution of the second oceanic assemblage (Table 3: oceanic assemblage B, with *Coryphaena hippurus*) in the 0 to 50 m depth stratum. 5C. Distribution of the ubiquitous mesopelagic species *Vinciguerria nimbaria* in the 50 to 100 m depth stratum.

Victor, 1987), but are probably not frequent or abundant components of larval fish assemblages at these distances (Leis, 1984; Clarke, 1991). Regional differences may exist, however, and the presence of island-associated taxa extends to a radius of 100 to 300 km from islands in the Pacific Ocean and 300 to 600 km in the Indian Ocean (Fedoryako, 1989). Aoki and Ueyanagi (1989) suggested that *Coryphaena hippurus* occurred in association with oceanic islands, whereas its congener *C. equiselis* was distributed throughout oceanic waters. *Coryphaena hippurus* was included in one of the groups within the oceanic assemblage around Johnston Island (Table 3; Boehlert et al., 1992). The distribution of this assemblage around the island, however, was regionally variable (Fig. 5B); it occurred in very low densities near the island and increased in density with distance offshore. *Vinciguerria nimbaria*, a species ubiquitous in distribution, also had lower densities near the island than offshore (Fig. 5C). This species and the oceanic assemblage (Fig. 5B) were least abundant in the area where the dominant neritic assemblage was found in highest abundance (Fig. 5A). This suggests that maintenance of locally spawned species occurred, as opposed to concentration of all species. The role of behavior in maintaining this distribution pattern is unknown.

Following Leis and Miller (1976), most studies have included larvae of insular species with planktonic eggs in oceanic assemblages, along with the widely distributed, truly oceanic species (Leis 1978, 1982; Miller et al., 1979). Similar results can be found in studies of larvae from Australia, a continental rather than insular system (Young et al., 1986; Leis and Goldman, 1987). It is interesting to note, however, that the only assemblage at Johnston Island with a mix of oceanic and island-related taxa included the Chaetodontidae and Scaridae, with a distribution pattern showing abundance in both neritic and oceanic waters (Table 3). Investigations are thus demonstrating that not all families, or even all taxa within families with pelagic eggs, are as widely dispersed in oceanic assemblages as previously thought (Leis, 1987, 1989; Boehlert et al., 1992). Resolution of these patterns will require more investigation with techniques that overcome the sampling problems noted by Clarke (1991).

*Physical and Behavioral Mechanisms.*—That islands, particularly in tropical regions, are areas of relatively high productivity seems to be related to vertical mixing and upwelling associated with current-topography interactions (Heywood et al., 1990). These interactions are different from those around seamounts and will not be reviewed in detail here. Instead, the focus is how these interactions relate to the formation, maintenance, and breakdown of larval fish assemblages. [For a more comprehensive background on island-current effects, see reviews in Hogg (1980), Hamner and Hauri (1981), and Wolanski and Hamner (1988).]

Formation and maintenance of embayment assemblages probably depend upon a combination of boundary-layer effects, longer retention times for water, and behavior of larvae. Retention of larvae may be proportional to flushing times (Sammarco and Andrews, 1989), and larger, deeper lagoons typically have longer flushing times; moreover, wind-driven, two-layered circulation patterns exist in atoll lagoons (Atkinson et al., 1981). It is thus possible that larvae can behaviorally alter horizontal distribution with vertical movements (Doherty et al., 1985). Boundary mixing in coral reef lagoons is responsible for virtually all of the vertical mixing (Wolanski, 1987), but there is some evidence that the magnitude of mixing is sufficiently low in embayments and lagoons to allow larvae to maintain position. Kobayashi (1989), for example, observed consistent patterns of larval fish distributions at differing distances from patch reefs, suggesting visually mediated behavior in this fine-scale distribution. Epibenthic behavior of postflexion larvae has been suggested to maintain larvae in specific areas (Leis et al., 1989; Breitburg, 1989); this presumably involves visual behavior and orientation to both the bottom and, in the case of schooling, to other individuals.

Physical mechanisms important for nearshore assemblages are similar but probably more varied. Localized benthic boundary layers may exist in certain areas with reduced flow, allowing aggregations of larvae (Hamner and Hauri, 1981). In contrast, highly turbulent mixing in surf zones would preclude position maintenance by larvae (Bakun, 1988). The larval fishes that have been observed in surf zones are typically later-stage larvae over relatively smooth bottoms (Senta and Kinoshita, 1985). Larger-scale interactions of currents and islands come into play as well for the nearshore assemblage. Laminar flow occurs at certain combinations of current speeds and island diameters; in laminar flow, the impinging current separates around the island and its entrained boundary layer. Thus, in gentle flows, there may be a boundary layer with little movement of water and moderately sized areas of very limited water movement ("stagnation points") both upstream and downstream (Hamner and Hauri, 1981; Fig. 1B). With increasing current flow, the thickness of this boundary layer decreases until a critical point is reached at which flow becomes turbulent. As a result, the distribution of nearshore assemblages around islands is not expected to be uniform. Regional differences in species composition (Leis, 1986b; Boehlert et al., 1992) may be a result. Thus, current speed, proximity to bottom boundaries, bottom type or roughness, and island morphology may all affect the maintenance of nearshore assemblages.

Factors important in the formation of neritic assemblages include attributes of adult spawning, passive aggregation of positively buoyant eggs, and behavior of larvae (Table 1). Fish eggs may be advected to localized areas, providing an aggregation mechanism from more spatially dispersed spawning (see summary in Shapiro et al., 1988). Passive concentration of positively buoyant eggs into windrows may later result in concentrations of larvae. This is best demonstrated for the buoyant eggs of corals (Wolanski et al., 1989; Black et al., 1990) but is not well documented for fish eggs. The distribution of fish eggs in the downstream, neritic region around Johnston Island (Boehlert et al., 1992), however, suggests that it may occur. Egg abundance in the upper 50 m of the water column showed highest densities downstream of the island (and in particular at a single station) in a moderately high background density (nearly 200 eggs$\cdot$1,000 $m^{-3}$). At 50 to 100 m depth, egg abundances were high immediately downstream of the island (Fig. 6), but were nearly zero at greater distances. This suggests either that certain species spawn in deeper water near the island or that vertical mixing occurs. In the former case, the egg abundance may be due solely to spawning distribution, whereas in the latter case, passive accumulation may form and maintain the observed distribution. It is interesting to note the similarity of the egg distribution in Figure 6 to that of the neritic assemblage in Figure 5A. The dominant species (*Eviota epiphanes*) in that assemblage (Table 3) has demersal eggs, while some of the other species have pelagic eggs. Although physical mechanisms resulting in passive accumulation are not unique to oceanic islands, they may play an important role in the formation of spatially restricted neritic assemblages.

Current-topography interactions are important to neritic assemblages of larvae. Theory holds that with increases in current speed, flow becomes turbulent and a stable eddy pair can become entrained in the downstream area; upstream and downstream stagnation points may remain (Fig. 1C). The scale of the eddy pair is on the order of an island diameter. With further increases in current speed, one of the two eddies will increase in size and vorticity until it is shed downstream, followed by buildup and eventual shedding of the other eddy (Fig. 1D). Larvae

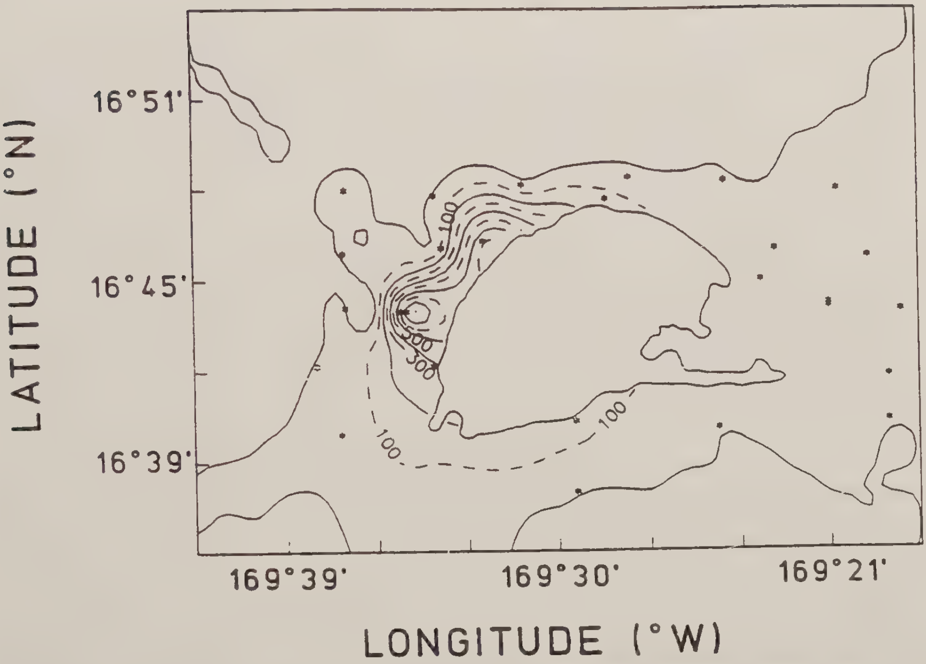

Figure 6. Distribution of fish eggs in the 50 to 100 m depth stratum around Johnston Island: the outline surrounding the island represents the 18-m isobath (from Boehlert et al., 1992). Density notations are eggs per 1,000 $m^3$.

may be retained in areas of limited water motion or in the entrained eddies. Larvae present in shed eddies will be advected from islands. Both physical and biological processes involved require more research, but they may affect the integrity and distribution of neritic assemblages.

Another theoretical mechanism that is pertinent to islands in tidally driven currents is rotary flow (Pingree and Maddock, 1985a). Observations at islands, however, are relatively limited: Pingree and Maddock (1985b) described movements of a drogue in waters surrounding a small island. Its behavior supported the predictions, with several clockwise loops around the island over a 3-day period. The relevance of this pattern to retention and maintenance of larval fish assemblages, however, is difficult to evaluate; little information was provided on the time scale of formation or retention of water masses around islands. Tidally generated eddies, however, are unlikely to remain near an island on the time scale important to recruitment (Wolanski and Hamner, 1988), and oceanic islands are typically less subject to tidal mixing and flow reversal as compared to islands on continental shelves (Bakun, 1988). The approach of Loder et al. (1988) could be beneficially applied in this situation. That is, analysis of time scales of water exchange in directions around an island (radially outward, rotary motions tangential to bathymetry, and in the vertical) would simplify highly complex flow patterns to allow interpretation of their role in biological phenomena.

The time scale of eddy retention is important to consider relative to assemblages. Downstream eddies with identifiable biological characteristics have been seen in several studies, but estimated time scales of water retention vary. Heywood and

Priddle (1987) estimate a minimum retention time of 11 days for an eddy characterized by high phytoplankton biomass observed downstream of King George Island in the Southern Ocean. Through downstream measurements of phytoplankton biomass, they suggested that only 50% of the phytoplankton was retained within the eddy during its residence at the island. Heywood et al. (1990) observed very distinct physical and biological features characterizing a trapped eddy downstream of Aldabra Atoll in the Indian Ocean, but it was absent 1 month later in slower flow conditions.

Upwelling in the lee of an island, as noted by Heywood et al. (1990), as well as along the flanks can interact with behavior to result in retention of larvae. Leis (1986b) suggested a related mechanism in the maintenance of larvae upstream of an island by upward swimming to maintain position in a downwelling feature. This is similar to proposed mechanisms of planktonic population maintenance through "winter cascading" off Bermuda (Boden and Kampa, 1953). The role of "linear oceanographic features" (Kingsford, 1990) may take many forms but, with appropriate behavior of the animals, can aggregate and potentially orient larval and juvenile fishes (Kingsford and Choat, 1986) in a landward direction. Tidally induced fronts may extend some distance (on the order of 2 km) from islands or reefs, thereby increasing the "effective size" of an island system (Kingsford et al., 1991).

Relatively little can be said about the nature of formation and maintenance of the oceanic assemblage. Eddy shedding from an island in a unidirectional current may develop a von Karman vortex street of eddies in downstream waters as observed by Barkley (1972) for Johnston Island. He suggested this wake would be detectable some 600 km downstream of that island. While this process would advect larval fish assemblages entrained in the eddy (presumably with species from the neritic and oceanic assemblages) far downstream, eddies from upstream along with their biological communities may be "trapped" by islands (Heywood and Priddle, 1987; Atkinson et al., 1990). Similarly, Dehknik et al. (1966) proposed that eddies transported oceanic larvae to the island of Cuba, as opposed to retaining larvae of nearshore species near the island.

*Interrelations Among Assemblages: Questions of Scale.*—As discussed above, the temporal and spatial bounds of ichthyoplankton assemblages around oceanic islands are poorly defined. Thus, it is difficult to evaluate the possible interrelationships among the four types of assemblages. Of the four, the spatial boundaries of the embayment and lagoon assemblage are best defined, yet little research exists on ichthyoplankton in these areas, unlike that in continental shelf islands (Leis, 1981, 1986a) or estuarine systems (Boehlert and Mundy, 1988). It is likely, however, that this assemblage has the best potential to maintain its integrity given the relative stability of the habitat and the microscale consistency of occurrence of certain species (Kobayashi, 1989). Similarly, the nearshore assemblage as defined by Leis (1978) may retain its integrity, possibly through visual orientation (i.e., bottom-oriented behavior) and use of microscale hydrographic features that may protect larvae from advection.

The neritic assemblages may be dependent upon small to mesoscale hydrographic processes and may thus be characterized by greater "leakiness" to the oceanic assemblage. Leis (1982) suggested that the neritic assemblage off Oahu may have been maintained by a small (ca. 3 km) tidally generated eddy with more stability than ocean current-generated eddies. Lobel and Robinson (1986, 1988), however, considered larger mesoscale eddies generated by local winds off the island of Hawaii as serving the same function. The scale, at some 50 to 150 km, clearly exceeds the bounds of the neritic zones as defined above, yet the dominant species observed by Lobel and Robinson (1988) are characterized as neritic in other studies (Table 2). Lobel and Robinson (1988) suggested that larvae could complete their development during the period in which the eddy remained near the island. That these eddies expand and move off to oceanic waters periodically (Patzert, 1969), however, suggests that they may carry away significant components of the neritic assemblage, which will dissipate with time into the ocean assemblage.

It would be difficult to determine the real offshore extent of the oceanic assemblage because of the rarity of larvae. Certainly larvae of shorefishes taken at vast distances from land (Victor, 1987) have a poor chance at settlement in an appropriate habitat. Given the nature of the problem and the costs of sampling on this scale, it is doubtful that significant progress will soon be made in greater definition of this assemblage.

## Summary and Conclusions

Evidence for the presence of unique ichthyoplankton assemblages is weak at best for small seamounts and equivocal at larger banks and seamounts. Some species seem to be adapted for transport of larvae away from these habitats. Seamounts may serve to disrupt oceanic ichthyoplankton assemblages through physical and biological interactions. Oceanic islands, on the other hand, have characteristic ichthyoplankton assemblages that have been described as embayment, nearshore, neritic, and oceanic. Even here, however, definition of the spatial and temporal dimensions of assemblages will require further work. The lack of identification of the assemblages by quantitative, replicated techniques means that they may only be considered as hypotheses of ecological associations. The absence of such investigations leads us to conclude our discussion of ichthyoplankton assemblages at seamounts and oceanic islands with two questions. First, "Do the proposed assemblages of fish larvae at seamounts and islands have ecological meaning?" The relationship to physical and biological factors, and the temporal and spatial robustness of island assemblages, require further attention before this can be answered. Second, "What role do these assemblages play in the maintenance of potential recruits in the two habitats?" Understanding this role may lead to improvements in our approach to dealing with questions of settlement and recruitment in seamount and oceanic island ecosystems.

## Acknowledgments

We thank H. G. Moser and P. E. Smith for their organizational work and for providing the stimulus to write this paper. We also thank C. D. Wilson, I. Hamann, and J. M. Leis for critical reviews of the manuscript.

# METHODS FOR ANALYZING INTERACTIONS OF LIMITED-RANGE FISHERIES: HAWAII'S PELAGIC FISHERIES

Christofer H. Boggs
Honolulu Laboratory

National Marine Fisheries Service, NOAA
Honolulu, Hawaii, USA

## ABSTRACT

A review of previous studies indicated that local fishing intensity can affect local pelagic fish abundance, but overall abundance on a wider scale may have a greater local effect. Interactions of limited-range fisheries were explored using a theoretical model in which local catch per unit effort (CPUE) declines as the catch approaches or exceeds the rates of fish immigration and recruitment in a limited area. The model has the local catch increase with effort to an asymptotic level. This simple model was used to simulate local CPUE in relation to varying rates of immigration and local fishing. Simulated data were used to test an analytical approach--the regression of CPUE on catch--which was then applied to real data from Hawaii's troll fishery. Analyzing CPUE in relation to catch rather than effort was convenient because fishing effort is poorly documented in Hawaii and includes effort by diverse methods. The analysis indicated that the CPUE of yellowfin tuna (*Thunnus albacares*) in Hawaii's troll fishery was not affected significantly by total yellowfin tuna catch in Hawaii in 1987-90, but was directly related to an index of abundance for surface-caught yellowfin tuna in the western Pacific.

## 1. INTRODUCTION

In Hawaii and in many Pacific island nations, locally-caught pelagic fishes constitute a small fraction of stocks that extend far beyond the range of the local fisheries. Primary concern over the status of these stocks is appropriately focused on abundance and production throughout their range (Suzuki, 1989). However, the rate of replacement of fish within any area is finite. Theoretically, if fishing mortality in an area increases greatly in relation to net immigration and recruitment, local catch per unit effort (CPUE) will decline. If there are several fisheries in such an area, fishery interactions may occur.

Fishery production models, which typically are used to estimate maximum sustainable yields for pelagic species (Suzuki, 1989; IATTC, 1992), are not very useful for detecting fishery interactions. Nor are they useful for estimating the optimal level of fishing effort in localized fisheries that are too small to significantly affect the size of the stock or its level of production (Sathiendrakumar and Tisdell, 1987). In many areas of the Pacific, including Hawaii, tropical tuna and billfish production may be limited mostly by immigration from surrounding areas rather than by the reproduction and growth of resident fish. For such fisheries, a model in which the local catch increases with effort towards an asymptote was proposed by Sathiendrakumar and Tisdell (1987).

In this paper, I develop a simple model for the relationship between catch and effort in a limited-range fishery on a highly mobile pelagic stock. The model is similar to that of Sathiendrakumar and Tisdell (1987) but is explicitly formulated as a function of immigration, emigration, natural mortality, and catchability. I use the model to simulate data for a fishery in which immigration, emigration, and fishing effort are seasonal. The simulated data are used to test whether the effect of fishing intensity on local catch rates can be adequately quantified by regressing CPUE on catch rather than on effort. Using catch rather than effort to quantify fishing intensity is helpful if total fishing effort is poorly documented and derived from widely different fishing methods, as is the case in Hawaii. Finally, the CPUE in Hawaii's troll fishery for yellowfin tuna (*Thunnus albacares*) is analyzed in relation to the total catch by troll, handline, and longline fisheries to determine whether the troll CPUE has been affected by total fishing intensity.

## 2. REGULATING LOCAL FISHING EFFORT IN HAWAII

Local fishery managers in the USA Exclusive Economic Zones (EEZs) of the central and western Pacific can do little about the distant-water foreign fisheries, which operate outside the EEZs and harvest the majority of pelagic fish caught in the region (NMFS, 1991). The primary USA fishery-management objective is to prevent recruitment overfishing (NMFS, 1989), defined in relation to pelagic populations which are mostly exploited beyond USA jurisdiction. This objective is dysfunctional, since there exists no international management organization through which stock-wide objectives can be achieved (NMFS, 1991). Therefore the USA Western Pacific Regional Fishery Management Council (WPRFMC) has focused its objectives on "equitable domestic utilization of the resources. . ." among user groups (WPRFMC, 1991). Recognizing that the domestic catch within the EEZs of the USA may be large enough to reduce local CPUE and cause local fishery interactions, the WPRFMC has attempted to regulate fishing effort in Hawaii's EEZ (WPRFMC, 1991).

Recent increases in the total catch of pelagic species in the USA Pacific EEZs have mostly been due to an expanding domestic longline fishery in Hawaii (Ito, 1991; WPRFMC, 1991). The less mobile, small-vessel troll and handline fisheries in Hawaii have experienced declines in total catch and CPUE (Boggs, 1991) as the longline fishery has expanded. Concern by troll, handline, and longline fishermen over reduced CPUE, together with gear conflicts, dangerous confrontations between fishermen, and overcrowding of dock facilities, induced the WPRFMC to pass regulations halting the entry of additional vessels into the USA domestic longline fishery in Hawaii in 1990. To prevent gear conflicts, the WPRFMC in 1991 also passed regulations closing nearshore areas (<50-70 miles, depending on location) to longline fishermen.

Scientific evidence in support of limiting longline-fishery participation in Hawaii has been sparse. Prior to 1986 the WPRFMC focused on the impacts of foreign longline fishing within Hawaii's EEZ on catch rates for pelagic management unit species (PMUS) which included billfish, mahimahi (*Coryphaena hippurus*), wahoo (*Acanthocybium solandri*), and pelagic sharks, but not tunas (Lovejoy, 1977, 1981; Wetherall and Yong, 1983; Skillman and Kamer, 1992). The possible impacts of foreign fishing in the EEZ were regulated by the original Pelagic Fisheries Management Plan (WPRFMC, 1986) but became irrelevant as no foreign longliners exercised the option to fish legally in Hawaii's EEZ after 1980. However, the expanding domestic longline fishery in Hawaii now catches more fish than the foreign longliners did before 1980 within the EEZ (WPRFMC, 1991). This catch increase, plus the inclusion of tunas as a Pacific Pelagic Management Unit Species (PPMUS) in 1992, provided some impetus to regulate the domestic fisheries.

Regulating fishing effort rationally requires a quantification of the effect of local fishing pressure on local CPUE for pelagic species, and a means of choosing a desirable level of fishing effort. An optimal level of fishing effort can be estimated if the cost of effort and the value of catch are defined and the relationship between catch and effort is quantified as an asymptotic curve (Sathiendrakumar and Tisdell, 1987). In the asymptotic catch model, although catch never declines because of overfishing, CPUE does decline as effort increases. Thus, detecting and quantifying an asymptotic relationship between local catch and fishing effort would help indicate whether regulating the local fishing effort is justified.

The optimization of fishing effort, in relation to the appropriate costs and benefits, depends on the relative mix of the fisheries comprising the total effort. Thus, the allocation of fishing effort among interacting fisheries is an additional problem. Changing the composition of effort by different gear types will alter the optimum. Furthermore, the decision as to which fishery to regulate, and how, may be strongly influenced by historical, social, or logistical considerations. For example, the least-mobile fisheries are most vulnerable to local declines in CPUE, and this could be a reason to limit the effort of the more mobile longliners in some areas rather than the effort of all the fisheries in those areas. In any case, evidence that local fishing pressure affects local CPUE should be the basis of any scheme for regulating fishing effort.

## 3. REVIEW OF PREVIOUS RESEARCH

Several previous studies suggest that localized fishing effort can reduce catch rates (CPUE) for wide-ranging pelagic stocks in a local area (Lovejoy, 1977, 1981; Wetherall and Yong, 1983; Squire and Au, 1990; Skillman and Kamer, 1992). Lovejoy (1977, 1981) simulated the pelagic fisheries in Hawaii's EEZ and predicted that small increases in the domestic catch of blue and marlin (*Makaira mazara*) and striped marlin (*Tetrapturus audax*) would result if foreign fishing in the EEZ was eliminated. Wetherall and Yong (1983) modelled blue marlin catch rates near Hawaii as a function of mid-Pacific abundance, recruitment, and fishing effort, and found that increases in local, adjacent, and mid-Pacific effort had negative impacts on CPUE near Hawaii. Skillman and Kamer (1992) found significant negative correlations between foreign longline effort and Hawaii's longline catch rates for blue and striped marlins. Most recently, Squire and Au (1990) found that local longline and troll catch rates of striped marlin rebounded when longline fishing was temporarily excluded from an area off Mexico. All of these studies found that local fishing effort affected local CPUE, but they lacked the appropriate model or sufficient data to accurately quantify the relationship, and thus provided no means of choosing an optimal intensity for local fishing effort.

The model of Lovejoy (1977) demonstrated that short-term abundance of transient populations was reduced by increasing local fishing effort, but the relative magnitude of the reduction was dependent on the actual (but unknown) number of fish in the area. Lovejoy (1977) used monthly Japanese longline CPUE data (1962-75) to model the spatial distribution, abundance, and catch of marlin in 27 subareas of Hawaii's EEZ and a single

Pacific (pooled) area. Fish movements through the EEZ were simulated to match geographic changes in Japanese CPUE in the 27 Hawaiian areas, assuming general north-south movements for blue marlin and northwest-southeast movements for striped marlin. However, the estimates of abundance and catchability were essentially guesses, and the catches predicted by the model were very sensitive to these parameters. This marlin-fishery simulation (Lovejoy, 1977) was repeated with the removal of the fishing mortality caused by longline fisheries in the EEZ (*i.e.*, set to zero). When Japanese longline fishing in the EEZ was eliminated, the changes in the fish abundance were small in areas fished by the small-vessel trollers, as were the effects of changes in abundance on troll catches of blue and striped marlins (2 and 5%, respectively). The simulated increases in troll catches were larger when domestic longline fishing also was eliminated (5 and 21%, respectively). Though smaller than the Japanese fishery in the EEZ at that time, the domestic longline fishery had a greater simulated impact because it had a greater geographic overlap with the troll fishery.

The sensitivity of the Lovejoy (1977) simulations to parameter estimates was illustrated when the estimated abundances of the marlin stocks were altered (Lovejoy, 1981). When the number of marlins moving from the Pacific-pooled area to Hawaii's EEZ was halved (Lovejoy, 1981) and catchability was increased to simulate the same catches as in the original model, eliminating all longline-fishing mortality increased the simulated troll catches of blue marlin by 13% and striped marlin by 45%, respectively. In contrast, when abundances were doubled, eliminating all longline fishing increased the troll catch of blue marlin by only 1% and striped marlin by 3%.

Exogenous factors may overwhelm the influence of local fishing effort on local catch rates of highly-mobile pelagic fish. Indices of abundance (CPUE) in local areas, for example, have been found to be significantly correlated with CPUE over a much wider range. Using Japanese longline catch-and-effort statistics for 1962-79 to compute estimates of abundance, Wetherall and Yong (1983) found that variation in blue marlin catch rates at the beginning of a year in a mid-Pacific area explained 80% of the annual variation in peak third-quarter catch rates in a 5x10 degree (latitude x longitude) area around the main Hawaiian Islands. No other statistically-significant predictors of local catch rates were found, but by including the variables for a recruitment trend and the foreign fishing effort in local, adjacent, and mid-Pacific areas, Wetherall and Yong's (1983) regression model increased the amount of accountable variation from 80% to 95%. Their analysis suggests that the impact of local effort on Hawaii's blue marlin fishery was small compared with the impact of abundance on a wider scale, under the conditions prevailing in 1962-79.

Pronounced seasonal cycles characterize the local, apparent abundance of large, tropical, pelagic species, especially towards the higher latitudes. The effect of local effort on CPUE may well depend on the season. Wetherall and Yong (1983) and Squire and Au (1990) accounted for seasonal effects by eliminating all but the data for the season of peak CPUE. Another method used by Skillman and Kamer (1992) was to decompose the seasonal and nonseasonal components of quarterly and monthly time series and examine the nonseasonal component. At a quarterly resolution, deseasonalized, local, domestic longline CPUE statistics for blue and striped marlins in Hawaii (1962-78) were significantly negatively correlated with foreign longline effort in local and adjacent areas ($P < 0.05$), whereas no significant correlation was found at the annual resolution

(Skillman and Kamer, 1992). The correlation coefficients were low (-0.26 to -0.32, nonparametric Spearman coefficients), and no attempt was made to quantify the relationships. Domestic longline CPUE statistics were most negatively correlated with Japanese longline effort in the local area, again suggesting a stronger relationship with increased proximity.

An unintended "experiment" on the effect of local fishing effort on local marlin CPUE was performed by the government of Mexico in 1977 when it enforced regulations against foreign longline fishing within its 200-mile exclusive economic zone. The enforcement caused a major decrease in fishing effort, allowing an interesting comparison to be made between catch rates before and after 1977 (Squire and Au, 1990). Striped marlin catch rates by troll fishermen in the area west of Mazatlan and around the tip of Baja California doubled during 1977-80 (Squire and Au, 1990). Joint-venture longline operations beginning in 1979-80 in the area also experienced catch rates twice as high as those in 1976. This series of events suggests a much stronger effect of local fishing effort on CPUE than that indicated for Hawaii's fisheries (Lovejoy, 1977; Wetherall and Yong, 1983; Skillman and Kamer, 1992). The opportunity to make a comparison like that of Squire and Au (1990) between CPUE statistics before and after the abatement of foreign longline fishing in Hawaii's EEZ (1980) was given as a reason for regulating foreign longline fishing (WPRFMC, 1986). Unfortunately this analysis was never undertaken, partly because of a severe decline in reporting of Hawaii's fishery statistics beginning around 1979 (S. Pooley, Honolulu Laboratory, National Marine Fisheries Service, Honolulu, HI 96822-2396, unpubl. manuscr.).

Squire and Au (1990) described the Mexico striped marlin fishery as operating in a "core area" in which fish naturally aggregate in concentrations that are much higher than throughout the population range. When they analyzed catch rates of the joint-venture fishery and the foreign longline fishery off Mexico in relation to fishing effort during 1962-84, they found no clear quantitative relationship. This was largely because the CPUE in the core area declined in 1981-84, despite relatively low levels of effort. Squire and Au (1990) suggested that a reduction in core-area fishing effort disproportionately raises the local CPUE, because core-area CPUE depends more on the formation and fishing down of "hot spots" than on stock production. Hypothetically, the relationship between fishing effort and CPUE in "hot spots" could be different from that in a larger area. Such a relationship could be demonstrated only if the data had very fine geographic resolution.

## 4. ASYMPTOTIC MODEL FOR LOCAL CATCH

A model for a local fishery in which the catches reach an asymptote as fishing effort increases was proposed by Sathiendrakumar and Tisdell (1987) to determine the optimal level of local fishing effort. I propose a similar model except that the parameters are defined in relation to immigration, emigration, mortality, and catchability. Emigration is treated as if it were analogous to natural mortality, so the two are combined. In the simplest case of this model (*i.e.*, assuming steady-state equilibrium and constant "natural mortality" and catchability), the asymptotic maximum catch is governed by the level of immigration (Figure 1). The parameters and derivation of the model are as follows (all fluxes--immigration, catch, and mortality--are annual, and numbered expressions are considered axiomatic):

$I$ = local immigration (metric tons)--analogous to biological production but independent of local biomass;

$C_i$ = catch (metric tons) at effort level i;

$f_i$ = effort ($10^3$ hooks) at level i;

$q$ = catchability ($1/10^3$ hooks) [assumed constant];

$F_i$ = fishing mortality [$F_i = qf_i$]; (1)

$M'$ = "natural mortality" including emigration [assumed constant],

$Z'_i$ = total "mortality" including emigration [$Z'_i = M' + qf_i$]; (2)

$B_i$ = equilibrium biomass (metric tons) in the local area [$B_i = I/Z'_i$]; (3)

$C_i = B_i F_i$ (metric tons); (4)

$$C_i = \frac{IF_i}{Z'_i} \text{ (metric tons)} \qquad \text{[from (3)];}$$

and

$$C_i = \frac{Iqf_i}{M' + qf_i} \text{ (metric tons)} \qquad \text{[from (2)].}$$

The example shown (Figure 1) uses arbitrary values: $I$ = 5,000, 10,000, and 20,000 metric tons, $q$ = 0.0001/1,000 hooks, and $M'$ = 0.06. When fitting the model to data where $I$, $q$, and $M'$ are unknown, the model can be simplified:

$$\text{If} \quad a = \frac{Iq}{M'} \quad \text{and} \quad b = \frac{q}{M'} ,$$

$$\text{then} \quad C_i = a\left(\frac{f_i}{1+bf_i}\right) \text{ (metric tons).}$$

Algebraic manipulation of the model equation yields the following linear relationship between CPUE and catch (Figure 2):

$$\frac{C_i}{f_i} = a - bC_i \quad \text{(metric tons/10}^3\text{ hooks)},$$

which makes the model easy to fit.

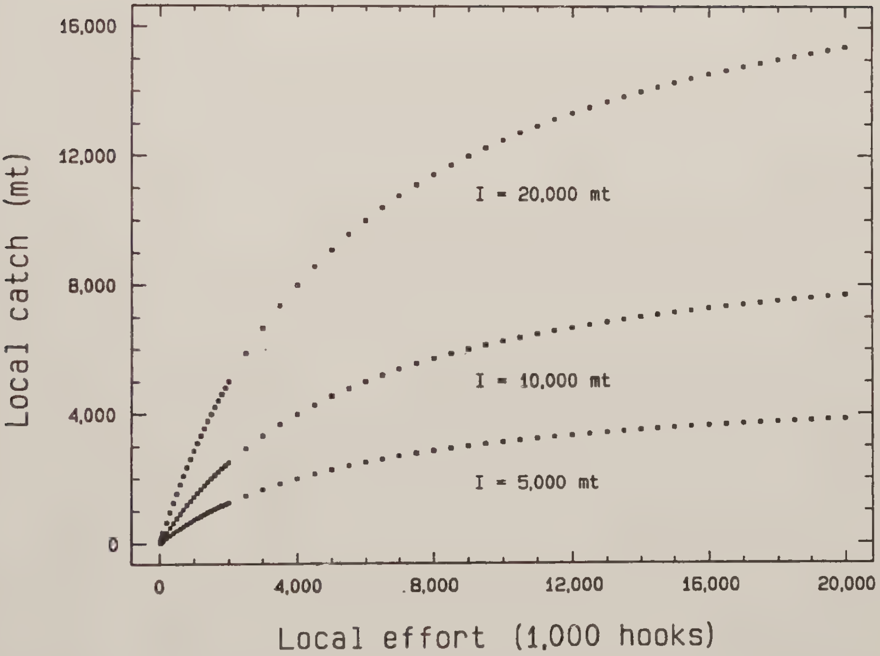

Figure 1. Asymptotic catch model for a limited-range pelagic fishery that catches a small fraction of the stock of a highly-mobile pelagic species. Natural mortality, emigration, and catchability are constant, and the local biomass of fish is at equilibrium. Annual immigration (I) determines the annual asymptotic catch in metric tons (mt).

Unfortunately, in reality, immigration, emigration, and effort vary seasonally, and equilibrium is not achieved instantaneously. A more realistic model was created by making immigration, natural mortality (plus emigration = $M'$), and fishing effort vary according to annual cycles, with effort also increasing over time. Simulated data were obtained by calculating the catch, mortality, and the resulting nonequilibrium local biomass at 10 time steps per day for 4 years, summarized by month (Figure 3). The annual cycles of immigration and emigration were chosen to produce a cycle of local biomass roughly resembling the pattern seen in CPUE data from Hawaii's yellowfin tuna fisheries.

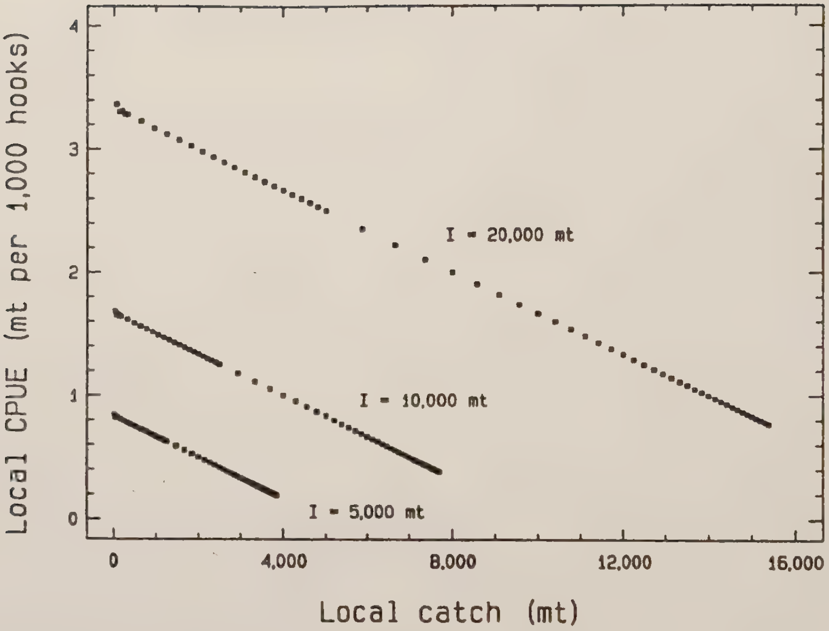

Figure 2. Relationship between local CPUE and total local catch in metric tons (mt) according to the asymptotic catch model in Figure 1.

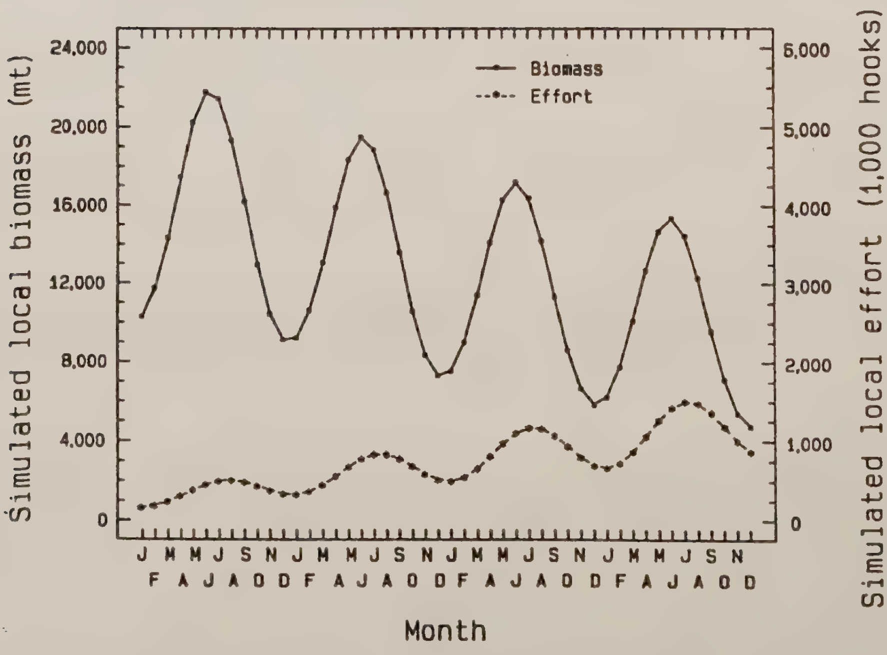

Figure 3. Simulated monthly biomass in metric tons (mt) and fishing effort in a limited-range fishery like that in Hawaii. Immigration, emigration, and effort vary in an annual cycle, and effort increases threefold over 4 years. Local biomass is not in equilibrium.

When the simulated CPUE data and catch are plotted, there is a clear relationship between CPUE and catch, although the slope is different for each month of the year (Figure 4) in keeping with the monthly changes in $I$, $M'$, and $F$. The nonlinearity of relationships for each month is due to lag effects under nonequilibrium conditions (the nonlinearity disappears when CPUE for each month is plotted *versus* catch for the 5-month period ending that month). Ignoring the nonlinearity, multiple regression of seasonally-adjusted CPUE on catch and first-order interactions between catch and months explains 96% of the variance in the simulated data, suggesting that this simple analytical approach could work with real data. However, the simulated data contain no random components which might obscure weak relationships.

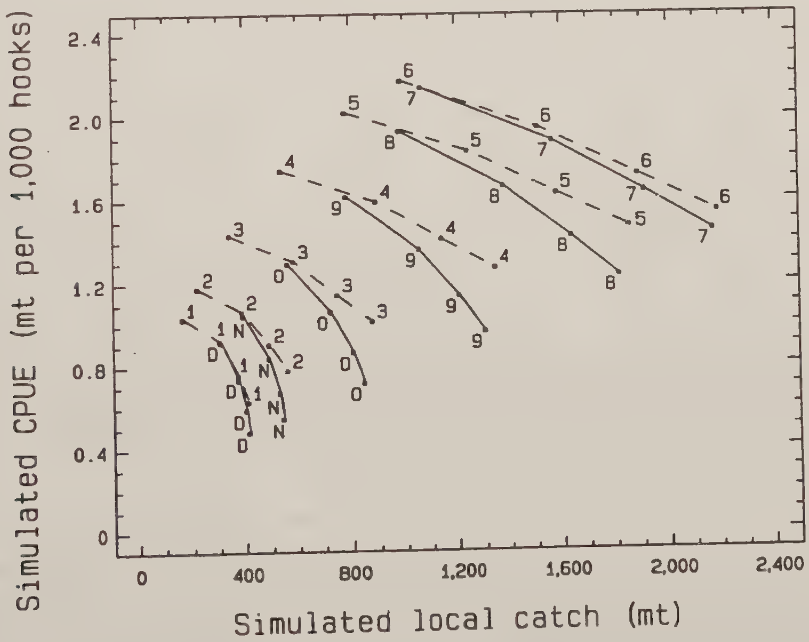

Figure 4. Simulated local catch per unit effort (CPUE) plotted versus simulated local catch in metric tons (mt) for the limited-range fishery model with seasonal variation and increasing effort as in Figure 3. Relationships between CPUE and catch for the first (dashed lines) and last (solid lines) 6 months of each year are identified by characters (1-9 for January-September, and O, N, D for October, November, and December, respectively).

Further realism was added by making immigration vary annually as well as seasonally. When immigration was reduced by 40% in alternate years, the resulting relationship between simulated CPUE and catch was hard to perceive (Figure 5). However, using a dummy variable (1 or 0) for high and low immigration years (and including first-order interactions between immigration and months) made it possible to use multiple regression to describe the slopes and intercepts of the CPUE- *versus*-catch relationships for each month and level of immigration (Figure 5). These slopes and intercepts were then used to compute the asymptotic relationships between catch and effort (Figure 6).

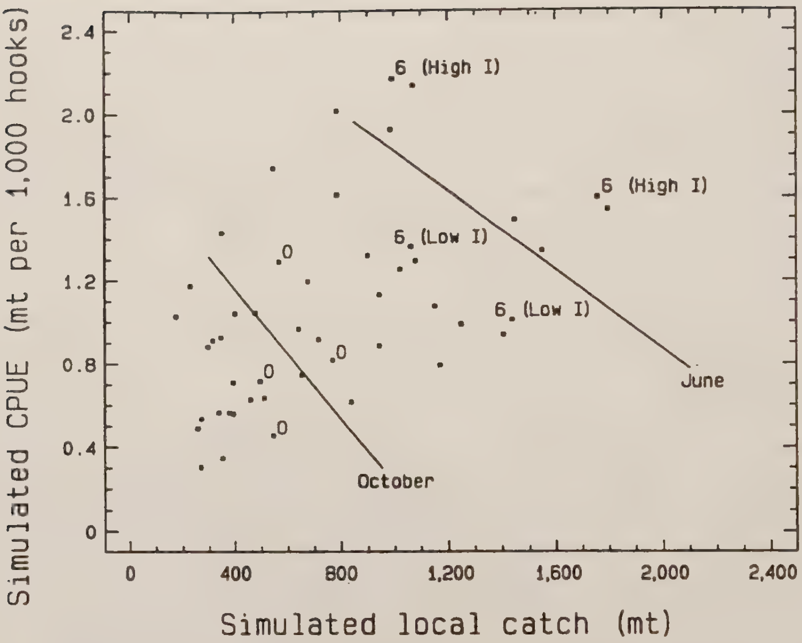

Figure 5. Simulated local catch per unit effort (CPUE) plotted versus simulated local catch in metric tons (mt) for the limited-range fishery model with immigration (I) alternating from high to low (40% less than high) in alternate years. Relationships for an average amount of immigration, calculated with the multiple regression analysis are shown for June (points labelled 6) and October (points labelled O).

In reality, local immigration is an unknown quantity, but the apparent abundance of fish over a larger area can be used as an index of immigration in a multiple regression analysis of real data. It is logical that more fish would immigrate in years when they are more abundant in the surrounding area, and this behaviour would be consistent with work showing strong correspondence between the apparent abundance of pelagic fish in local areas and abundance on a wider scale (Wetherall and Yong, 1983; Squire and Au, 1990; Skillman and Kamer, 1992). Another mechanism that would explain the correspondence in apparent abundance would be widespread changes in catchability. In contrast, changes in immigration or local catchability due to localized environmental conditions would not be consistent with the observed correspondence in apparent abundance, and thus the local environment may represent an additional source of variation.

The simulations illustrate how relationships between catch and effort within a limited area may differ seasonally and annually. The optimal level of fishing effort may be highly dynamic, making the rational management of fishing effort difficult. Analyzing CPUE data *versus* catch should at least be useful for detecting an impact of local fishing pressure on local CPUE, even when that impact differs seasonally and annually. Detecting such an impact however may require quantifying variation due to other factors.

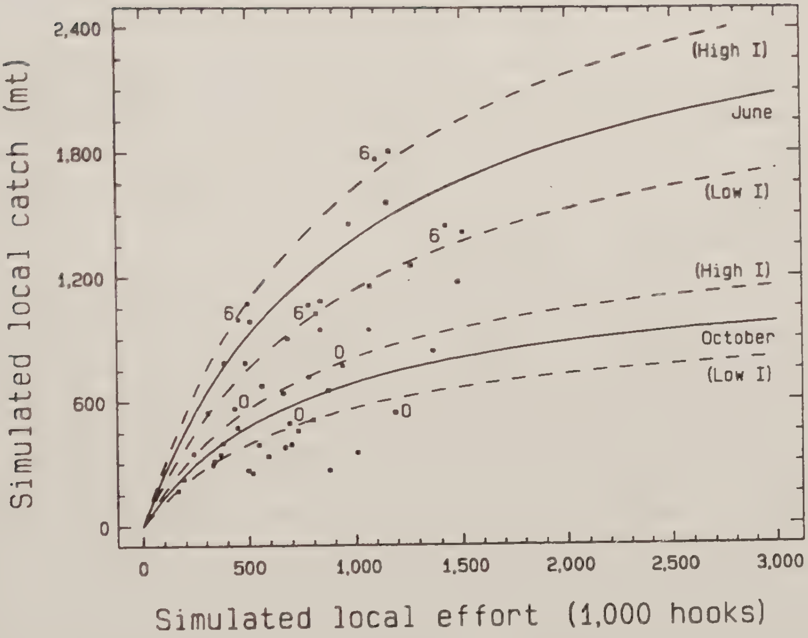

Figure 6. Asymptotic catch relationships for monthly local catches in metric tons (mt) as a function of monthly local effort in a limited-range fishery from the analysis of simulated data shown in Figure 5. The relationships for high and low immigration (I) years (dashed lines) differ from the average relationship (solid lines) for each month (June data labelled 6; October data labelled O).

## 5. YELLOWFIN TUNA CPUE IN HAWAII

In a preliminary study (Boggs, 1991), troll and handline CPUE data (pounds per trip) were plotted *versus* longline catch to determine whether relationships appeared that might be indicative of fishery interactions. This graphical inspection of the CPUE *versus* catch data was applied to yellowfin tuna, bigeye tuna (*Thunnus obesus*), blue and striped marlins, mahimahi, and wahoo. In the preliminary study (Boggs, 1991), the analyses covered data for January 1987-June 1990. The present study extends the analysis through the end of 1990 for yellowfin tuna troll CPUE (pounds per trip) and compares troll CPUE with the total catch (by all fisheries) rather than just the longline catch.

The data used to calculate troll catch per trip (CPUE) were provided by the Hawaii Division of Aquatic Resources (HDAR) as summaries of commercial catch (pounds of fish) by year (1983-90) and month (1987-90) along with summaries of the total number of fishing trips per year or month, respectively. Annual and monthly catch rates were calculated as the ratio of total catch (in pounds) to the number of trips. No geographic categorization of the data was used, but most of the troll fishing was conducted within 50 miles of shore around the eight main Hawaiian Islands. The HDAR catch data did not contain reports of trips; rather, each date for each vessel in the records was counted as a trip if any PMUS or tuna was reported caught. The assumption of 1-day trips is fairly realistic for the small-vessel troll and handline fisheries.

Catch per trip may not be a good measure of yellowfin tuna abundance since important operational changes and improvements in trolling methods have undoubtedly occurred over the years. The catch per trip index contains no data from trips with zero catches, no standardization of trips as a unit of effort, no estimate or correction for underreporting, and no estimate or correction for changes in reporting over time. Any of these factors could bias trends or relationships in the data, or give the appearance of a trend or relationship where none exists.

Despite these potential problems, catch per trip as an abundance index can provide some indication of changes in the local abundance or availability of fish to trollers and handliners in Hawaii. Catch per trip indices based on HDAR data often mirror patterns seen in more sophisticated CPUE indices, such as catch per hook or catch per set, from nearby fisheries (Wetherall and Yong, 1983; Skillman and Kamer, 1992). When the data from several different sources show a similar pattern, those data probably indicate a true pattern of apparent abundance unless some unknown bias affects several sources of data similarly. In any case, catch per trip is the only available measure of CPUE for Hawaii's troll and handline fisheries. More definitive examinations of trends in CPUE will require data that more accurately specify fishing effort.

Annual troll CPUE (pounds per trip) for yellowfin tuna declined from a relatively high level in 1979 to low levels in 1982-84 (WPRFMC, 1991). Troll CPUE for yellowfin tuna returned to high levels in 1987, dropped again and remained low through 1989, and showed some recovery in 1990 (Boggs, 1991). The decline in troll CPUE for yellowfin tuna in 1987-1989 corresponded with a period of dramatic expansion of Hawaii's domestic longline fishery (Boggs, 1991; Ito, 1991; WPRFMC, 1991), suggesting that some fishery interactions may be occurring. The low troll CPUE seen in 1982-84, however, occurred before the domestic longline fishery expanded and after the foreign longliners ceased fishing in Hawaii's EEZ, suggesting that periods of low troll CPUE may be unrelated to longline fishing effort.

The total longline catch, as estimated by the National Marine Fisheries Service (NMFS) shoreside monitoring programme, showed increasing monthly variation and an upward trend from 1987 through 1989, levelling off somewhat (annual average) in 1990 (Figure 7). The longline catch estimates were for the entire range of the longline fishery, mostly within the Hawaii EEZ but extending beyond it. The range of the troll and handline fisheries is much smaller and is roughly centred within the area fished by the longline fishery (these data precede the establishment of nearshore area closures for longline fishing).

The NMFS data rather than the HDAR data were used to estimate longline catch because they cover most of the longline catch in Hawaii, whereas the HDAR data cover only a small fraction of that catch. Conversely, the NMFS market sample data cover only a fraction of the troll and handline catch and do not distinguish between these two gear types, which have markedly different catch rates. Therefore to obtain total catch, the HDAR data on the catch by gear other than longline (mostly troll and handline) were combined with NMFS estimates of the longline catch. A potentially large component of

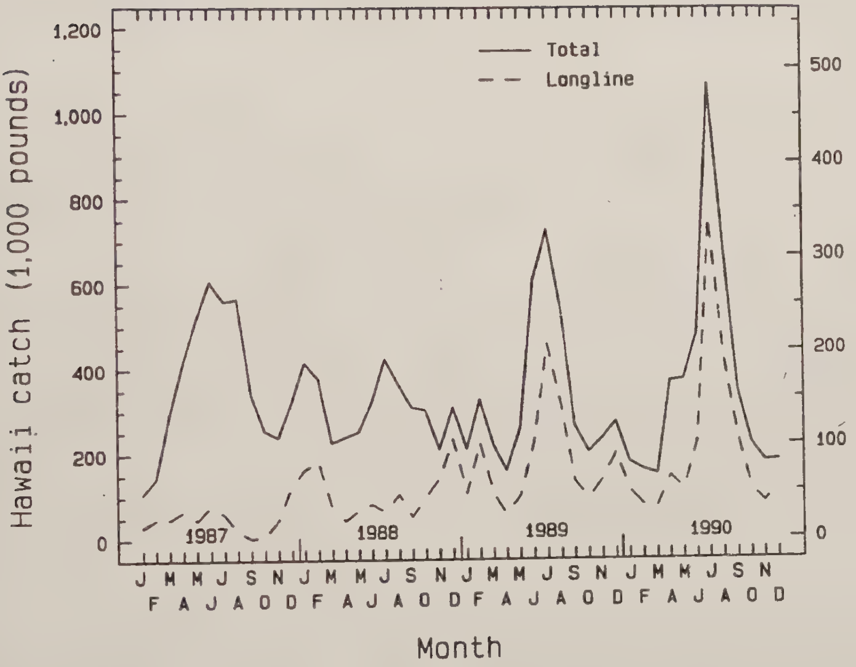

Figure 7. Total catch (all gear types combined, in pounds and metric tons) and longline catch of yellowfin tuna in Hawaii each month in 1987-90. Longline catch is estimated from the shoreside monitoring programme of the National Marine Fisheries Service, and the remainder of the total is from the non-longline catches in the commercial catch reports of the Hawaii Division of Aquatic Resources. The recreational catch is not known.

the total catch, namely the recreational catch, remains unquantified, and there are no good estimates of under-reporting by commercial troll and handline fishermen. Thus, total catch is known with less certainty than longline catch, which was one reason Boggs (1991) used only longline catch.

The total catch of yellowfin tuna by all gear types (Figure 7) varied monthly in 1987-90 but did not show much of an annual trend. As catch by the longline fishery increased, catch by the other fisheries decreased. Fishermen have suggested that increased longline catch might be causing the decline in troll and handline catch; this is why troll and handline CPUE was plotted *versus* longline catch in Boggs (1991). However, examination of CPUE in relation to total catch is more appropriate since the catch by trollers and handliners would also be expected to contribute to any local reduction in biomass.

Hawaii's trollers, handliners, and longliners depend on the same size range of fish to provide the bulk of their yellowfin tuna catch, so interactions of these fisheries are possible. Even though the troll and handline size-frequency distribution (combined) includes more small (<50 lb) fish than the longline size-frequency distribution (Ito, 1991), the small fish add relatively little to the weight of troll and handline landings (Figure 8). The combined troll and handline data (Figure 8) are mostly from Oahu where trolling predominates. Handline-caught fish tend to be even more similar in size to longline-caught fish. The reason for the decreasing catch of small fish (Figure 8) is not known.

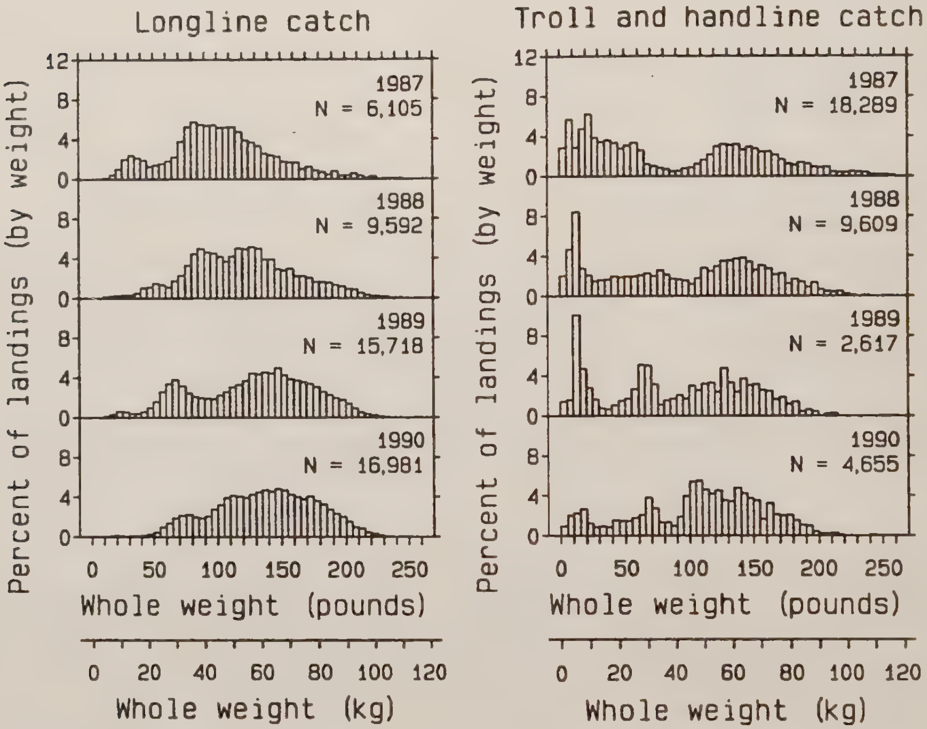

Figure 8. The proportional landings (percent of total weight landed) by weight category (pounds and kg) in Hawaii's longline and combined troll and handline fisheries. Weights of fish were obtained by the National Marine Fisheries Service shoreside monitoring programme (N = number of fish). The combined troll and handline samples are from Oahu, where trolling is the predominant small-vessel pelagic fishing method.

Changing operational characteristics in recent years make longline trips a poor measure of effective effort. For the same reason, longline-catch per trip is a poor measure of yellowfin tuna abundance and thus has not been examined. Troll and handline trips differ from each other and from longline trips in their relative effectiveness, making total effective effort difficult to estimate. Thus, total catch, rather than effort, was used as a more convenient estimate of fishing pressure.

In the preliminary analysis by Boggs (1991) of the monthly data from 1987 to June 1990, six species were examined, but only yellowfin tuna had CPUE values that appeared to be negatively related to longline catch. The relationship was clearest when monthly CPUE was plotted *versus* longline catch for the 3-month period ending the same month. Months were categorized by Boggs (1991) as "in-season" and "nonseason" to account for seasonal effects, whereas the present study used multiple regression analysis of seasonally-adjusted CPUE data on catch with interaction terms for each month.

The apparent relationship found in the preliminary study may have been due to chance, since very low troll and handline catch rates were also observed in 1982-84, well before the longline fishery expanded. Unfortunately, good estimates of total catches for the earlier period are not yet available. Estimates for this earlier period may be developed if market data from this period can be obtained from fish dealers.

When the troll CPUE data for the 48-month period from 1987 to 1990 were analyzed in relation to total monthly yellowfin tuna catch in the present study, no relationship was apparent (Figure 9). An analysis of handline CPUE gave similar results. As in Boggs (1991), the CPUE data for each month were also analyzed in relation to longline catch, and longline catch for the 3-month period ending that month, but still no relationship was found. This was due to the addition of 6 months of new data from 1990, wherein the CPUE increased over 1989 levels despite continued high levels of longline catch (Figure 10).

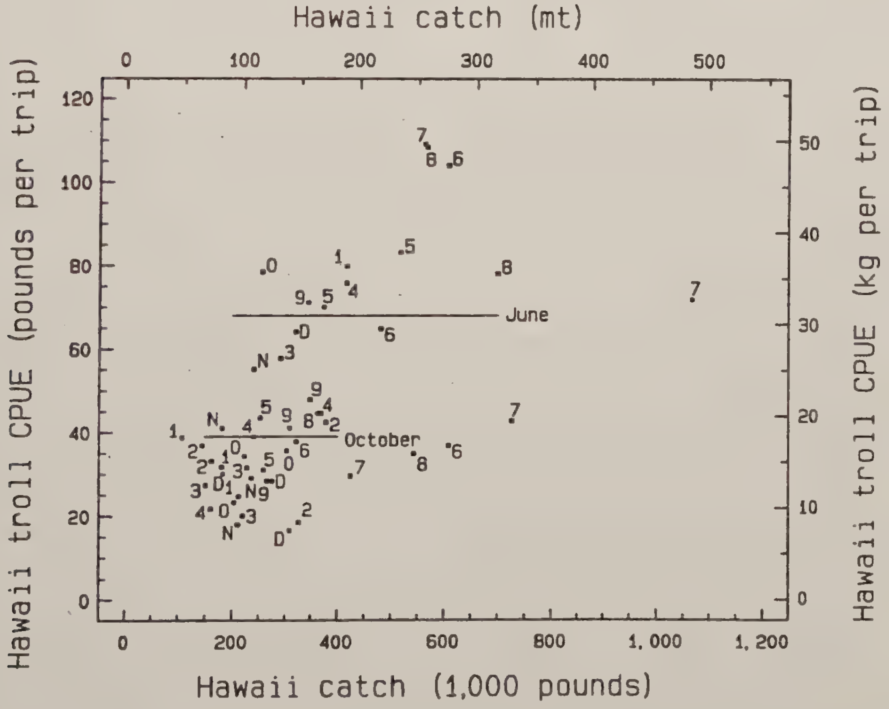

Figure 9. Observed monthly yellowfin tuna catch per unit effort (CPUE) (pounds per trip and kg per trip) in Hawaii's troll fishery, versus total monthly yellowfin tuna catch by all fishing gears (labelled as in Figure 4) for 1987-90. The lack of any CPUE versus catch relationships (slopes ≈ 0) based on multiple regression analysis is shown for June and October.

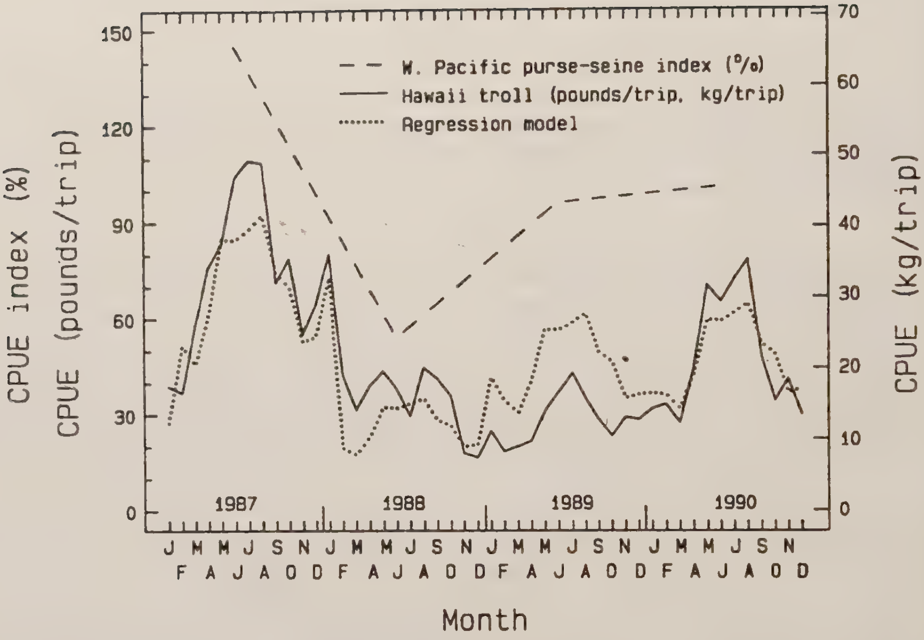

Figure 10. **Observed catch per unit effort (CPUE) (pounds per trip and kg per trip) for yellowfin tuna by Hawaii's troll fishery for each month in 1987-90, and the annual index of wide-scale abundance of yellowfin tuna from the USA and Japan purse-seine fisheries (percent of average CPUE). Predicted local CPUE from a regression of seasonally-adjusted CPUE on the purse-seine index is also shown.**

An index of wide-scale surface yellowfin tuna abundance from purse-seine fisheries in the western Pacific (Figure 10) was added to the regression analysis to see whether removing some of the interannual variation in immigration would reveal an underlying relationship between local CPUE and fishing intensity. The purse-seine index was calculated as the geometric mean of CPUE from the USA (Coan, 1993) and Japan (Suzuki, 1992) purse-seine fisheries in the western Pacific, expressed as a percent of mean CPUE (Figure 10). This index was the most significant factor ($P < 0.0001$) in a multiple regression of seasonally-adjusted local CPUE on total catch, the purse-seine index, and first order interactions by month.

Catch was not a significant factor (slope ≈ 0, Figure 9). The predicted CPUE, based on the seasonal adjustment and regression analysis, followed the pattern of observed CPUE fairly well (Figure 10). It seems that seasonality and the exogenous supply (*i.e.*, the immigration rate) of yellowfin tuna are the dominant factors affecting local CPUE, and the available evidence suggests that local CPUE was independent of local levels of exploitation in 1987-90.

It should also be noted that the purse-seine index may not necessarily represent increases in wide-scale biomass or increased local immigration. Instead it may reflect a widespread change in catchability caused by environmentally-induced changes in behaviour and vulnerability to fishing gear.

There is clearly a need for more research on the local distribution dynamics of tropical pelagic species. Simulation models could be much more helpful if more was known about true abundance and fish-movement dynamics. Tagging studies would be a good way to get such information, if they coincide with improved fisheries data collection emphasizing the geographic distribution of fishing effort and catch. The results of previous studies make it clear that local fisheries data alone may not provide evidence of existing fisheries interactions, because of the important effects of exogenous factors such as changes in stock-wide abundance and catchability. Environmental influences on fish movements and catchability may also play an important role that must be investigated.

## 6. ACKNOWLEDGMENTS

The NMFS data summaries for this study were provided by Sam Pooley (NMFS Honolulu Laboratory), and the HDAR data summaries were provided by Reggie Kokubun (State of Hawaii Department of Land and Natural Resources) and Reese Tokunaga (NMFS Honolulu Laboratory).

# Hawaii's Pelagic Fisheries

CHRISTOFER H. BOGGS and RUSSELL Y. ITO

*ABSTRACT—Hawaii's diverse pelagic fisheries supply the bulk of the State's total catch. The largest Hawaii fishery is the recently expanded longline fishery, which now lands about 4,400 metric tons (t) of broadbill swordfish,* Xiphias gladius; *1,500 t of bigeye tuna,* Thunnus obesus, *and 3,000 t of other pelagic species annually. The increased catch of these other species has raised concerns regarding the continued availability of yellowfin tuna,* T. albacares; *blue marlin,* Makaira mazara; *and mahimahi,* Coryphaena hippurus, *in the small-vessel troll and handline fisheries which target those species.*

*Analysis of catch per unit effort (CPUE) statistics from Hawaii's fisheries did not provide strong evidence of recent declines in availability related to local fishery expansion. A more influential factor was variation in Pacific-wide CPUE, representing overall population abundance and catchability. Exogenous factors, including Pacific-wide fishing pressure, may overwhelm the influence of local fishing pressure on fish availability.*

## Introduction

Hawaii's pelagic fisheries are small in comparison with other Pacific pelagic fisheries (NMFS, 1991), but they are the largest fisheries in the State (Pooley, 1993b), and much larger than other U.S. island-based fisheries in the western Pacific (Hamm et al.[1]). Stocks of tuna, billfish, and other tropical pelagic species supply most of the fish consumed by Hawaii residents and support popular recreational fisheries.

In recent years (1987–91) the composition and magnitude of Hawaii's commercial pelagic fisheries have changed. The longline fishery greatly expanded and the troll, handline, and pole-and- line fisheries declined (Ito[2]). The expansion of the longline fishery was consistent with fishery development plans that viewed pelagic fish resources as underexploited (State of Hawaii Division of Aquatic Resources (HDAR) 1985). Pelagic fish resources available to Hawaii fisheries may be capable of sustaining even greater yields. However, the decline of the troll and handline fisheries has raised concerns regarding the continued availability of pelagic species and local overfishing (Boggs[3], Ito[2]).

Pelagic fish availability is synonymous with local abundance, here defined as the amount of fish present within the range of the local fishery. Overall abundance refers to population size, which is greater than local abundance unless the entire population resides within range of the local fishery. The stock structure of large pelagic species is unclear, but a common assumption is that pelagic populations extend over much wider areas than are covered by Hawaii's fisheries (Skillman, 1989a, 1989b; Suzuki, 1989, In press; Miyabe, In press).

Availability probably depends on overall abundance, but the availability of fish to Hawaii's pelagic fisheries is also highly seasonal (Shomura, 1959; Yoshida, 1974; Skillman and Kamer[4]), suggesting that highly mobile pelagic fish change their distribution in response to environmental conditions (Seckel, 1972; Mendelssohn and Roy, 1986), or to enter different areas for reproduction. Availability may also be confounded with catchability, defined as the vulnerability of fish to being caught by a given type of fishing gear. Catchability is also influenced by environmental conditions (Sharp, 1978; Hanamoto, 1987).

The limited mobility of most island fishermen causes yield to be poor when availability is low. Intense local fishing effort is not likely to cause a decline in overall abundance unless there are discrete stocks residing in, or periodically returning to, island waters. Otherwise, the fishing mortality caused by Hawaii fisheries is minor compared with overall fishing mortality caused by larger Pacific fisheries. Thus, local fishing pressure is unlikely to cause a significant reduction in overall abundance.

Even though locally exploited pelagic stocks may be wide-ranging, and relatively invulnerable to local fishing pressure, catch per unit effort (CPUE) in local fisheries may decline if local fishing effort is so intense that most

fish entering the local area are soon caught. It is hypothesized (Sathiendrakumar and Tisdell, 1987; Boggs, In press) that if fish availability depends on immigration, increases in local fishing effort result in an asymptotic yield, beyond which further increases in local effort do not increase the catch, and local CPUE declines. The possible impact of local fishing effort on the CPUE and profitability of Hawaii's pelagic fisheries is currently an issue of great concern to Hawaii's fishery managers (Boggs[3], In press).

This paper describes Hawaii's longline, troll, and handline fisheries for pelagic species, trends in landings and CPUE over time, and problems with the data used to monitor these fisheries. Changes in the apparent relative availability of fish (local CPUE) are reviewed in relation to local fishery expansion and overall abundance (Pacific-wide CPUE). Current attempts at managing for optimum yield and the outlook for these fisheries are described. The Hawaii skipjack tuna fishery is covered in a separate paper (Boggs and Kikkawa, 1993).

## Synopsis of the Fisheries

The fishing methods, target species, vessel sizes, yields, and operational areas of Hawaii's domestic pelagic fisheries are diverse. The commercial sectors are largely composed of the pole-and-line and longline fisheries utilizing large (>12 m) vessels. The small-vessel troll and handline fisheries include poorly differentiated commercial, recreational, and subsistence components. The pole-and-line fishery targets skipjack tuna, *Katsuwonus pelamis,* and lands about 1,000 metric tons (t), (2.2 million lb) annually for sale to the local market (Boggs and Kikkawa, 1993). The longline fishery targets broadbill swordfish, *Xiphias gladius;* and bigeye tuna, *Thunnus obesus*, and now lands about 9,000 t (20 million lb, including all species) much of which is exported. The commercial, recreational, and subsistence troll and handline fleets primarily target yellowfin tuna, *T. albacares*; mahimahi, *Coryphaena hippurus*; and blue marlin, *Makaira mazara*; annual commercial landings (all species) now average about 2,300 t (5.2 million lb). No valid estimates exist for current recreational or subsistence landings (Pooley, 1993a).

Up until 1980 distant-water longliners from Japan caught between 1,300 and 5,000 t of tuna and billfish annually within the Exclusive Economic Zone (EEZ) around Hawaii (Yong and Wetherall, 1980) but since 1980 there has been no legal foreign longline fishing conducted in the EEZ. The Fishery Management Plan (FMP) enacted by the Western Pacific Regional Fishery Management Council (WPRFMC) was designed to regulate billfish catches by these foreign distant-water longliners (WPRFMC[5]). The Japanese distant-water pole-and-line fishery for skipjack tuna that operated in the Northwestern Hawaiian Islands (NWHI) through 1992 was the only foreign fishery operating legally within the EEZ after 1980 (Boggs and Kikkawa, 1993).

Although the primary target species of the domestic longline fishery are different from those of the troll and handline fisheries, the longline fishery also catches about 1,300 t (2.8 million lb) of yellowfin tuna, blue marlin, and mahimahi (combined). This creates a potential for fishery interaction between the longline and small-vessel troll and handline fisheries. Potential interactions, impacts on endangered species, the possibility of localized overfishing, and gear conflicts (Pooley, 1990) prompted the WPRFMC to establish regulations for the domestic longline fishery in 1990 (Dollar and Yoshimoto[6]). A moratorium on entry of longline vessels into the Hawaii fishery and prohibited areas for longline fishing were established in 1991.

## The Longline Fishery

### Fishing Methods

Longline fishing gear consists of a main line strung horizontally across 1–100 km of ocean, supported at regular intervals by vertical float lines connected to surface floats. Descending from the main line are branch lines, each ending in a single, baited hook. The main line droops in a curve from one float line to the next and bears some number (2–25) of branch lines between floats. Fishing depth depends on 1) the lengths of the float lines and branch lines, 2) the sag in the main line, and 3) the position of the branch line, the deepest branch line positions being in the middle of the droop. Fishing depth affects the efficiency with which different species are captured (Hanamoto, 1976, 1987; Suzuki et al., 1977; Boggs, 1992).

One longline "set" is made per day of fishing, and for long main lines the deployment and retrieval may take almost 24 hours. Often the end of the line deployed first is retrieved last, so individual hooks may fish for a few hours, or all day (average ca. 12 hours). Traditionally the gear was set so that it fished primarily during daylight. For bait, Hawaii longliners used locally caught scad, *Decapterus* and *Selar* spp.; imported squid, *Loligo* sp.; sardines, *Sardinops caerulea*; herring, *Clupea pallasi*; and saury, *Cololabis saira*.

The Hawaii longline fishery began in 1917 off Waianae, Oahu, using techniques imported from Japan. Hawaii longline vessels evolved from the wooden sampan-style baitboats used in the pole-and-line fishery for skipjack tuna (June, 1950). The sampans used in the early years of the fishery (ca. 1950) were 12–19 m (40–63 ft) in length, high-bowed, and diesel-powered. They carried about 12 t of ice to chill an average catch of about 3 t (7,000 lb) of fish caught over an average trip of 10.5 days (June, 1950).

Old-style longlines were made of rope and composed of individual units called "baskets" named for the bamboo containers they were stowed in (June, 1950). Each basket was made

up of the float line, main line, and branch lines necessary for one segment of longline (one droop of the line). Poles with flags were attached to the floats to mark the gear, and longlining was generally referred to as "flagline" fishing.

### Historical Development and Decline

Historically, the longline fishery was the second largest commercial fishery in the state after the pole-and-line fishery. By the 1930's longliners landed most of the 1,000 t (ca. 2 million lb) of yellowfin tuna, bigeye tuna, and albacore, *Thunnus alalunga*, landed in the Territory of Hawaii (June, 1950). After a hiatus during World War II the fishery quickly recovered, landing 900 t (2 million lb) of tuna, and 700 t (1.5 million lb) of billfish and other species in 1948. Landings continued to rise, reaching a record level of 2,000 t (4.4 million lb) in 1954 (Fig. 1A). The longline fishery declined in the late 1950's through the mid-1970's to reach a similar level of landings as the commercial troll (Fig. 2) and handline (Fig. 3) fisheries.

In the early years most of the catch was reported to have been in HDAR statistical areas 2–20 n.mi. (3.7–37 km) off Waianae, Oahu, and off Kona, Hilo, and Hamakua, Hawaii (June, 1950). Shomura (1959) reported greatly improved catch rates for bigeye tuna by longline vessels fishing off the windward coasts (i.e., Hilo) in winter as opposed to the traditional practice of fishing off sheltered leeward coasts (i.e., Waianae, Kona). Hida (1966) reported a growing number of longliners extending their range 100–400 n.mi. south of Oahu, and noted that CPUE was better than average in the southern area.

The species composition of longline landings changed over time. During 1951–64, more than 50% of longline landings (by weight) were bigeye tuna, also called ahi (a Hawaiian name), ahi mebachi, or "bluefin." True bluefin tuna, *Thunnus thynnus*, are rarely caught by Hawaii fishermen. Before 1950 and in the 1970's bigeye tuna and yellowfin tuna (also called ahi) made up roughly equal proportions of the catch (Fig. 1A). The proportion of blue marlin in the catch was higher than that of striped marlin, *Tetrapturus audax*, in the early 1950's but striped marlin became more predominant from the early 1960's to the present (Fig. 1A). Both marlin species are also called au (the Hawaiian name) or "swordfish," but they should not be confused with broadbill swordfish (Fig. 1B), which became the primary target species in the 1990's (Dollar[7]). Local common names for the pelagic species are often used for reporting catch statistics, resulting in some confusion.

The decline of the Hawaii longline fishery in the late 1950's through mid-1970's was characterized by a lack of new investment. Only a few new steel or fiberglass boats were built or added to the fleet between 1950 and 1982. Only 3 out of 11 boats surveyed in 1982 were built after 1970 (Hawaii Opinion[8]). Most longline vessels oper-

ating through 1982 were veterans of the 1940's and 1950's. Low profitability probably contributed to the lack of investment in new vessels.

Local sale of fresh fish, mostly for raw consumption, provided a limited market that was easy to saturate, driving down the price (Otsu, 1954). The Hawaii fresh-fish market was the only outlet, because mainland U.S. consumers did not accept tuna as a fresh product. The Japan "sashimi" market was distant and exacted hard-to-meet product standards. Prices offered by tuna canneries were too low to provide adequate profits.

Although the number of vessels declined, the amount of fishing gear deployed in an average trip nearly doubled between the 1950's (Shomura, 1959) and the early 1980's (Hawaii Opinion[8]). The number of hooks per basket, and consequently the length of main line between float lines, also increased, resulting in a deeper gear configuration. A similar shift in gear configuration characterized the distant-water longline fleets of Japan and Korea (Suzuki et al., 1977; Yang and Gong, 1988).

The number of vessels participating in the Hawaii longline fishery over the years is difficult to document because many vessels fished part-time while participating in other Hawaii fisheries. June (1950) identified 49 vessels as primarily longliners (30 in Honolulu), whereas Hawaii Division of Aquatic Resources (HDAR) records indicate 76 registered longline vessels in 1950. Yoshida (1974) states that participation declined from 42 vessels in 1952 to 31 in 1964, and to 20 in 1970. Yuen[9] reported that the longline fleet in Honolulu numbered 15 in 1977, and by 1983 HDAR records showed only 13 registered longline vessels (10 in Honolulu).

The decline in vessels corresponded with the declining trend in longline landings reported to HDAR between 1954 and 1982 (Fig. 1A). However, visual inspection of the Honolulu fleet in 1983 found 37 vessels carrying longline gear (Honda[10]) as opposed t 10 registered with HDAR. Incomplete reporting to HDAR prompted the establishment of a NMFS market sampling program in late 1986 (Pooley, 1993b) and a Federal longline logbook program (Dollar and Yoshimoto[6]) was instituted by the WPRFMC in 1990 t collect more detailed data. A compari-

son between NMFS estimates of longline landings at wholesale markets and landings reported to HDAR in 1987 showed that less than 20% of longline landings were reported (Ito[2]).

The best available estimates of Hawaii longline landings over time (Fig. 1A) are based on three data sources and a correction to account for underreporting (Pooley, 1993b). HDAR longline data are believed to be relatively complete through 1978 (Pooley, 1993b). NMFS estimates based on market sampling and logbooks (Ito[2]; Pooley, 1993b) are used for 1987–91 (Fig. 1A and 1B). Estimates for 1979–86 (dashed lines, Fig. 1A) are interpolated values between HDAR reported landings in 1978 and NMFS estimates for 1987 (Pooley, 1993b). In contrast, HDAR troll (Fig. 2) and handline (Fig. 3) landings reported to HDAR through 1991 are very similar to NMFS estimates (Pooley, 1993b), and HDAR troll and handline data are used in this paper without correction. The corrected longline data indicate that the nadir of the longline fishery occured in 1975 (not 1982, Fig. 1A).

### Revitalization and Expansion

The longline fishery expanded rapidly in the late 1980's to become the largest fishery in the state. The revitalization was due to the development of the local markets and export markets for fresh tuna on the U.S. mainland and in Japan (Kawamoto et al.[11]) and the introduction of new swordfish fishing methods in the late 1980's (Dollar[7]). Participation in the Hawaii longline fishery approximately doubled from 37 vessels in 1987 to 75 in 1989 (Ito[2]) and doubled again to 156 (vessels with permits) by the end of 1991 (Dollar and Yoshimoto[6]). Permits were required by the Federal moratorium on new entrants established in 1991. Only 140 of the vessels with permits were active in 1991. In 1988 landings data first exceeded the record set in 1954 (Fig. 1A) and by 1991 landings reached 9,000 t (20 million lb), including 4,400 t (9.6 million lb) of swordfish (Fig. 1B).

New entrants in the longline fishery were mostly steel-hulled vessels up to 33 m (107 ft) in length, and the majority of these vessels and their operators were former participants in U.S. east coast tuna and swordfish fisheries (Dollar[7]). The present fleet uses modern electronics (Radar, Loran, Global Positioning System (GPS)) to navigate, and uses radio beacons, strobe lights, and radar reflectors to mark the gear. Some vessels obtain sea-surface temperature maps by radio-facsimile (FAX) and most have electronic thermometers for use in finding fish associated with temperature fronts.

Changes in fishing methods and greater amounts of fishing gear characterized the expansion of the longline fleet. In 1988 most vessels still used basket-type, rope longline gear, but they deployed over 3 times as much gear on an average trip as vessels in 1982 (Hawaii Opinion[8], Kawamoto et al.[11]). A few vessels used "bin" gear in which the rope mainline is continuous, rather than composed of baskets, and these vessels deployed similar amounts of gear as those using basket gear (Kawamoto et al.[11]). Continuous nylon monofilament main lines stored on spools and used with snap-on monofilament branch lines were first used in 1985, and by the end of 1988, 29% of the fleet used this new system (Kawamoto et al.[11]). Monofilament gear was popular among new entrants to the Hawaii fishery and became the most prevalent gear type in the fleet. Longliners using monofilament gear tended to deploy over four times as much gear per trip in 1988 (Kawamoto et al.[11]) as was typical of the fleet in 1982 (Hawaii Opinion[8]).

Monofilament longline gear is more flexible in configuration and can be used to target various depths more easily than basket gear because the amount of main line, the number of branch lines, and the sag between floats are adjustable. This flexibility was demonstrated by the switch from traditional deep daytime fishing for bigeye tuna to shallow nighttime fishing, targeting broadbill swordfish in the 1990's (Ito[2]). Both daytime and nighttime methods are still practiced using the same monofilament longline system. In targeting bigeye tuna 12–25 hooks are deployed between floats with lots of sag to reach as deep as 400 m (Boggs, 1992), whereas in targeting swordfish only a few hooks are deployed between floats and the line is kept relatively taut so that it stays in the upper 30–90 m of water. Night fishing employs luminescent "light sticks" which attract broadbill swordfish and bigeye tuna or their prey (Berkley et al., 1981). Large imported squid, *Illex* sp., are used for bait.

A special "line thrower" is required to put sag into a monofilament longline as it is deployed (Kawamoto et al.[11]; Boggs, 1992) so that it can fish deeply for bigeye tuna. Many new entrants to the fishery in 1989–91 did not invest in line throwers. These vessels fished shallow even when targeting tuna (daytime fishing) and probably contributed to the increase in the relative proportions of yellowfin tuna, blue marlin, and other shallow-swimming species caught by longliners in recent years (Fig. 1A). The increasing longline catch of these species was cause for concern by the small-vessel troll and handline fisheries that target them (Boggs[3]).

The fishing grounds of the Hawaii longline fishery expanded in the 1980's and 1990's. Hawaii fishermen interviewed in 1982 reported that they had to fish farther away from port in order to make good catches (Hawaii Opinion[8]). In 1986 Hawaii longliners began exploring fishing grounds up to 800 n.mi. from the main Hawaiian Islands, and distant-water fishing is becoming more common in the 1990's. Logbook data from the first quarter of 1991 indicate that over half of longline sets were more than 50 n.mi. away from the main Hawaiian Islands, and <2% of sets were made outside the EEZ (NMFS[12]).

Conflicts with other fisheries and interactions with protected species led to the exclusion of the longline fishery from nearshore waters in the 1990's. In early 1991 longline fishing was prohibited within a radius of 50 n.mi. off the NWHI (Dollar[7]) to prevent interactions between endangered Hawaiian monk seals, *Monachus schauinslandi*, and surface-fishing longliners that targeted aggregations of swordfish near those islands. In 1989 an informal agreement was negotiated between small-vessel fishermen and longline fishermen whereby longliners would keep >20 n.mi. from the coasts of the main Hawaiian Islands and >10 n.mi. from fish aggregating devices (FAD's). Some vessels, especially subsequent entrants to the fishery, did not comply with the agreement. To mitigate conflicts between longliners and small-vessel troll and handline fishermen, the WPRFMC in mid-1991 established a buffer zone prohibiting longline fishing within a radius of 75 n.mi. off the coasts of Kauai and Oahu, or within a radius of 50 n.mi. off the coasts of Maui, Molokai, Lanai, Kahoolawe, and Hawaii (Dollar and Yoshimoto[6]).

## The Troll Fishery

Troll and handline fisheries in Hawaii have not been studied as extensively as the longline fishery. Trolling involves towing lures or baited hooks behind a moving vessel, whereas handlining involves dangling baited hooks from a stationary or drifting vessel. The evolution and operation of the Hawaii troll fishery are poorly documented. Trolling with lures for pelagic species was a traditional Polynesian fishing method, and Hawaii has since been the site of important innovations in big-game troll fishing techniques (Rizzuto, 1983).

The troll fishery has several components: 1) a recreational-subsistence sector which is poorly differentiated from a part-time commercial sector, 2) a charter sector which is recreational for its patrons but commercial for the operators who sell the catch, 3) a part-time commercial sector, and 4) a full-time commercial sector. Most troll vessels are small (5–8 m, 15–25 ft in length), although charter boats range up to 18 m (59 ft). In the mid-1980's large (20–26 m, 65–85 ft) troll vessels transiting the Hawaii EEZ to fish for albacore, *Thunnus alalunga*, in the North Pacific participated briefly in the Hawaii troll fishery, and vessels from the lobster and bottomfish fisheries also participate intermittently in the Hawaii troll fishery. Troll fishing is conducted throughout the Hawaiian islands, generally within 20 n.mi. of shore.

Commercial catch reports to HDAR do not distinguish between different types of troll fishing (i.e., part-time, charter); only fishermen who sell their catch are required to file reports. Reported annual commercial troll catches were <200 t (0.4 million lb) until 1974 (Fig. 2). During 1975–84 catches ranged between 540–790 t (1.2–1.7 million lb) per year, and then the catch rose to a record peak of almost 1,700 t in 1987. Annual catches declined after 1987 but remained >1,000 t (2.2 million lb) through 1991 (Fig. 2).

The troll fishery catches more mahimahi and wahoo, *Acanthocybium solandri*, than all the other Hawaii pelagic fisheries, about half the blue marlin, and about 20% of the yellowfin tuna landed. Yellowfin tuna composed almost half the commercial troll catch from 1975 to 1980, after which its proportion in the catch declined. The proportion of mahimahi and skipjack tuna in the troll catch increased through the 1980's and 1990's. The charter sector of the troll fishery targets blue marlin, and this species accounted for 54% and 39% of estimated charter catches in 1976 (Cooper and Adams[13]) and 1982 (Samples et al.[14]), respectively. In contrast, 87% of full-time commercial troll catches were yellowfin tuna (Cooper and Adams[13]). Changes in the relative size of the different commercial sectors (i.e., charter, part-time) may influence the species composition of the total reported catch (Fig. 2).

Charter vessels in the troll fishery numbered 102 and 119 in 1976 and 1982, respectively (Cooper and Adams[13]; Samples et al.[14]), compared to an estimated 160 full-time commercial, and 1,544 part-time and recreational-subsistence trollers (combined) in 1976 (Cooper and Adams[13]). Proportions of the total troll catch by these sectors in 1976 were 21% charter, 44% part-time commercial and recreational-subsistence (combined), and 35% full-time commercial. About 70% of the charter catch and 60% of the part-time commercial and recreational-subsistence catch was sold (Cooper and Adams[13]). Growth of the troll fishery makes it unlikely that these proportions represent the current situation but the charter fishery is believed to have grown with the expansion of tourism, and the recreational-subsistence fishery remains important (Pooley, 1993a).

## The Handline Fishery

There are several types of pelagic handline fishing in Hawaii today. Day-handline fishing is a revitalization of an ancient Hawaiian method called "palu-ahi" for the use of "palu" (chum) to attract and hook ahi (yellowfin tuna). Palu-ahi fishing is also called "drop stone" fishing. A baited hook on the end of the handline is laid against a stone and the line wound around it. Additional pieces of chum are also wound into the bundle which is then tied in a slip knot (Rizzuto, 1983). The bundle is lowered to the preferred depth (commonly 20–30 m). Then the line is jerked to untie the knot so that the baited hook and chum are released.

Night-handline fishing is called "ika-shibi" from the Japanese names for squid (ika) and tuna (shibi). The ika-shibi fishery is an outgrowth of a squid fishery that probably began in the 1920's and did not target tuna until after World War II (Yuen, 1979). Ika-shibi fishermen attract squid to the fishing vessel with a light and catch the squid on jigs or with a gaff. The squid are then used as bait. Ika-shibi or palu-ahi were not distinguished as separate fishing methods in HDAR statistics prior to 1982. Subsequently (1982–91) only a fraction of handline landings were reported as palu-ahi or ika-shibi, and so the handline catch statistics have been combined for this report (Fig. 3).

[13] J. C. Cooper and M. F. G. Adams. 1978. Preliminary estimates of catch, sales, and revenue of game fish for the fishing conservation zone around the main Hawaiian Islands, by types of troll and longline vessels and by species. U.S. Dep. Commer., NOAA, Natl. Mar. Fish. Serv., Southwest Fish. Cent., Honolulu Lab., Southwest Fish. Cent. Admin. Rep. 24H, 10 p.

[14] K. C. Samples, J. N. Kusakabe, and J. T. Sproul. 1984. A description and economic appraisal of charter boat fishing in Hawaii. U.S. Dep. Commer., NOAA, Natl. Mar. Fish. Serv., Southwest Fish. Cent., Honolulu Lab., Southwest Fish. Cent. Admin. Rep. H-84-6C, 130 p.

All handline catches were sold on the Island of Hawaii where the fishery was primarily located until 1971 when the rising price for tuna and reduced shipping costs made air shipment to Honolulu economically feasible. The increasing market for fresh fish boosted the development of Hawaii's fisheries in the mid-1970's (Pooley, 1993a). Annual commercial handline landings reported to HDAR increased from 45 t to almost 1,000 t between 1970 and 1981. Since 1981 commercial handline landings have ranged between 500 and 1,000 t (1.1–2.2 million pounds) with major peaks in 1981, 1983, 1986, and 1991 (Fig. 3). The magnitude of the recreational-subsistence sector of the handline fishery is unquantified, but important (Pooley, 1993a).

The composition of the handline catch is almost exclusively tuna; yellowfin tuna is the predominant species (Fig. 3). Mahimahi and other nontuna species make up less than 10% of the catch. Bigeye tuna are an important component of the handline catch (Yuen, 1979) that is not reflected in HDAR statistics. The ika-shibi catch of bigeye tuna ranged from 63 to 120 t (139–265 thousand lb) in 1973–75 (Yuen, 1979), but HDAR records indicate <23 t of tuna other than yellowfin landed by all handline fishing gears in 1973–75 (Fig. 3). This may represent a lack of reporting, but it is also likely that handline fishermen are lumping both bigeye and yellowfin catches as ahi in their catch reports since these species have the same Hawaiian name.

Most handline vessels are 6–9 m in length and are often crewed by 1–2 persons. Surveys by Yuen (1979) and Ikehara[15] indicate that the ika-shibi fishery grew from 30–40 boats in 1976 to at least 230 boats by 1980. In recent years some of the smaller longline vessels and larger commercial troll vessels have also done some handline fishing.

Day-handline fishing was concentrated around the Island of Hawaii and ika-shibi fishing was concentrated off the Hilo coast of Hawaii in the mid-1980's. Traditionally, handline fishing was conducted within a few km of the coast at locations called "ahi koas" where yellowfin and bigeye tuna were especially available. The State (HDAR) encouraged expansion into new areas in the late 1980's. Handline fishing techniques have spread and are now practiced on Kauai and Maui. Some of the largest handline vessels have extended their range to fish around seamounts and weather buoys 100–200 n.mi. from the coast. This new expansion of the fishery may have contributed substantially to the peak in catch reported in 1991, which followed four years of continuous decline (1987–90, Fig. 3). Some fishermen feel that there may soon be too many participants in the handline fishery, and the WPRFMC has been asked to institute a control date for this fishery in anticipation of possible limited-entry management.

The increasing cost of insurance has been a problem for small-vessel commercial fishermen. Many operators could not afford to keep up with rising insurance costs in the late 1980's and some, who weren't willing to risk their assets, stopped fishing. Another economic problem for the commercial troll and handline fisheries is a condition called burnt tuna syndrome (BTS) which discolors and gives a bad taste to sashimi as well as reduces its shelf life (Nakamura et al., 1987). BTS is prevalent in troll and handline-caught fish over 35 kg and uncommon in longline-caught fish. Proper handling can ameliorate BTS (Nakamura et al., 1987) and research is under way to find means to prevent it (Watson et al., 1988).

## Abundance and Availability

### Background

The primary concern in Hawaii's pelagic fisheries today is whether fishing effort should be limited to protect the local abundance or availability of fish (Pooley, 1990; Boggs[3], In press; Skillman et al., 1993). Increased catches by Hawaii's pelagic fisheries over the last two decades could hypothetically have reduced the abundance of local stocks, if such stocks exist. It is more likely that Hawaii's fisheries exploit locally available fractions of Pacific-wide stocks (Wetherall and Yong[16]; Skillman and Kamer[4]; Boggs, In press). In the latter case immigration may limit yields and excessive fishing effort might result in reduced CPUE (Sathiendrakumar and Tisdell, 1987; Boggs[3], In press). In either case, excessive local fishing pressure should be evidenced by corresponding declines in local CPUE.

Several studies suggest that local fishing pressure can reduce local CPUE for wide-ranging pelagic species (Wetherall and Yong[16], Squire and Au, 1990; Boggs[3], In press; Skillman and Kamer[4]). Many of these studies also found that the relative abundance (CPUE) of fish over a wider geographic area could statistically account for much of the variation in local CPUE. Relative abundance estimated as CPUE is confounded with catchability, so that widespread environmental effects on catchability, as well as true changes in stock-wide abundance, could explain the statistical relationships between Pacific-wide CPUE and local CPUE.

The following examination of Hawaii CPUE time series extending from the early years of each fishery to the present was undertaken to show whether or not the expansion of Hawaii's pelagic fisheries over the last two decades, 1970–91, corresponded with declines in local CPUE. Major declines in local CPUE were often found to predate local fisheries expansion and corresponded with declines in the CPUE of more widespread fisheries. Over the last few decades the time series indicated much interannual variation and little net change in CPUE.

### Calculation of Hawaii CPUE

Longline CPUE was calculated from a combination of data sources including published literature, HDAR data summaries, and NMFS market sample estimates. Troll and handline CPUE was calculated solely from HDAR data summaries because these data identify troll and handline gears (NMFS estimates do not). HDAR summaries do not differ substantially (in total) from NMFS estimates for combined troll and handline (Pooley, 1993b). All available summary statistics (HDAR and NMFS) were used in the present study, but no new analyses of raw data were conducted.

To calculate CPUE in the early longline fishery (e.g., Fig. 4A), Hawaii longline data on two size-classes of vessels for 1948–56 (Shomura, 1959) were combined, and catch was converted from number of fish to weight. The results were similar to 1948–52 CPUE data published by Otsu (1954). The CPUE based on combined data differed little from the data for large vessels (Shomura, 1959), and although vessel size is important, it was ignored in the present study because data summaries by vessel size for subsequent years were not available.

Longline data summaries for 1959–89 and NMFS market sample longline estimates for 1987–89 (Ito[2]; Pooley, 1993b) were used to calculate longline CPUE for later years (e.g., Fig. 4A). HDAR longline data after 1978 are believed to represent only a fraction (ca. <20% Fig. 1A) of the fishery, but complete coverage is not required to calculate a representative CPUE index. No other data were available for 1979–86.

Two longline CPUE indices for 1987–89 were calculated, one from HDAR data, and another from NMFS estimates (e.g., Fig. 4A). The HDAR series from 1979 through 1989 best indicates the longline CPUE trend for those years, whereas the 1987–89 NMFS data best indicate recent CPUE for comparison with the earlier years 1947–78 (e.g., Fig. 4A). Longline CPUE was not calculated for 1990–91 because in these years a fraction of the longline fishery changed fishing methods to target broadbill swordfish, and additional work is needed to categorize the subset of the longline trips in 1990–91 that targeted tuna. The Hawaii swordfish fishery has developed too recently (Fig. 1B) for any trend in CPUE to be indicative of availability.

HDAR data summaries for the troll and handline fisheries from 1970 to 1991 were used to calculate CPUE time series for these fisheries (e.g., Fig. 4B). Prior data are not very important because the troll and handline fisheries were so small before 1970.

CPUE was calculated as the total annual longline, troll, or handline catch (by weight) of a species divided by total annual effort. Effort was estimated either as the annual number of fishing trips (troll and handline fisheries) or the annual number of hooks (longline fishery). Longline hook totals were calculated from the number of trips multiplied by estimates of hooks per trip (Boggs and Hawn[17]). Changes in the amount of gear deployed per trip obtained from descriptions of the fishery (June, 1950; Otsu, 1954; Shomura, 1959; Hida, 1966; Yoshida, 1974; Hawaii Opinion[8]; Kawamoto et al.[11]; Ito[2]) were used to estimate and interpolate the typical quantity of hooks per trip from 1947–89 (Boggs and Hawn[17]). Corrections for changes in efficiency with fishing depth are being developed (Boggs, 1992; Boggs and Hawn[17]) but are not used here.

The NMFS market sampling program counted fishing trips as each occasion that a vessel landed and sold its catch. HDAR data summaries included each unique date of landing for each unique license number in the records as a trip if any pelagic species were caught. Trip counts from both NMFS and HDAR data did not include trips with no catch of any pelagic species (prior to 1992). Such trips were seldom reported. For any given species the count of trips did include trips that did not catch that species but caught another pelagic species.

The lack of data on the number of trips that caught no pelagic species may have caused errors in the effort estimates, but the CPUE time series based on those data may still be indicative of relative changes in availability. The number of zero-catch trips should have been negatively correlated with catch per successful trip (CPUE) since both were dependent on fish availability. Thus, the CPUE time series should still reflect real trends, especially if zero-catch trips represented a modest fraction of total effort. No bias was caused by changes in the fraction of zero-catch trips reported because none were counted. Uchida (1976) found a high correlation between Hawaii pole-and-line CPUE including zero-catch trips and CPUE excluding zero-catch trips.

The effort data for the troll and handline fisheries contained no standardization of trips as a unit of effort, and the longline effort data were standardized only to account for changes in the number of hooks per trip (Boggs and Hawn[17]). Changes in troll or handline fishing power, (number of lines, hooks, or hours, per trip, etc.) or changes in longline, troll, or handline efficiency (class of vessel, gear type, target depth, fishing strategy) may have resulted in biases in the CPUE time series, obscuring trends or giving the appearance of trends where none existed. Although much of the data presented here are decades old, the estimates of CPUE must be considered preliminary until the raw data are reanalyzed and effort standardized to account for changes in efficiency (e.g., Uchida, 1976; Suzuki, 1989).

Despite problems with the nonstandardized CPUE indices, they are the only data currently available. Nonstandardized Hawaii CPUE data for several different gear types often show a similar pattern (Skillman and Kamer[4]) or reflect a pattern similar to that of more sophisticated CPUE indices from nearby fisheries (Wetherall and Yong[16]). These examples suggest that some true information on relative availability is represented by nonstandardized CPUE indices for Hawaii's fisheries.

[17] C. H. Boggs and D. R. Hawn. Changes in fishing power and estimates of fishing effort for the Hawaii longline fishery, 1948–91. NMFS Honolulu Laboratory, 2570 Dole St., Honolulu HI 96822–2396, unpubl. manuscr.

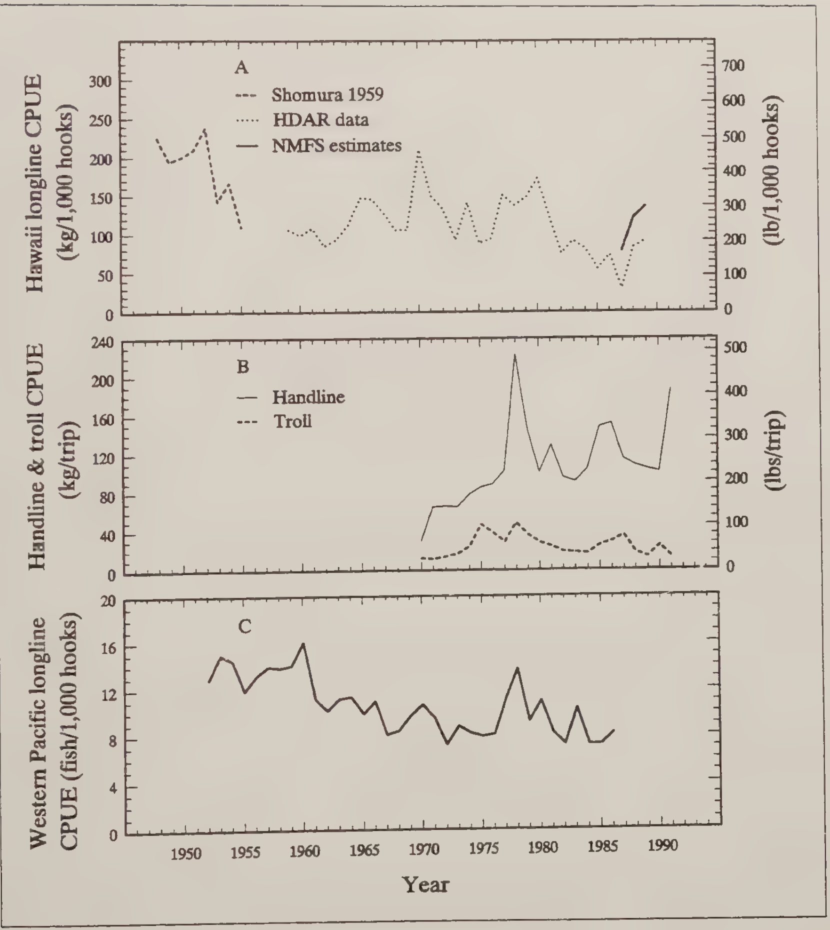

Figure 4.— Yellowfin tuna CPUE time series showing A) Hawaii longline CPUE (kg and lb per 1,000 hooks) from 1948–55 (Shomura, 1959), 1959–89 (HDAR data), and 1987–89 (NMFS estimates); B) Hawaii handline and troll CPUE (in kg and lb per trip) from 1970 to 1991 (HDAR data), and C) western Pacific longline CPUE (in no. fish per 1,000 hooks) in the Japanese fishery from 1952 to 1986 (Suzuki, In press).

### CPUE Time Series

Yellowfin tuna CPUE in the Hawaii longline fishery declined between the 1950's and the early 1960's and then ranged between 90–210 kg/1,000 hooks with no clear trend from 1959–81 (Fig. 4A). Yellowfin tuna CPUE based on HDAR longline data declined from 1980–87, recovering somewhat in 1988–89. The more accurate longline CPUE index based on NMFS estimates indicated a return to average longline CPUE in 1988–89 (Fig. 4A).

The 1980–87 decline in yellowfin tuna CPUE for the Hawaii longline fishery occurred during a period of troll (Fig. 2) and longline (Fig. 1A) fishery expansion. However, the subsequent increase in longline CPUE in 1988–89 occurred during the period of greatest longline fishery expansion, while troll and handline fishing levels remained very high. Thus low levels of Hawaii longline CPUE did not correspond consistently with periods of higher fishing pressure.

Yellowfin CPUE in the Hawaii troll and handline fisheries (Fig. 4B) increased from 1970 to 1978 and subsequently declined through 1984. After 1984 Hawaii handline and troll CPUE increased to peaks in 1986 and 1987, respectively, and then declined (Fig. 4B). These declines coincided with expansion of Hawaii's longline, troll, and handline fisheries. However, handline CPUE subsequently increased from 1884 to 1986 and troll CPUE increased from 1984 to 1987 despite continued expansion of the troll and longline fisheries. During the period of greatest expansion of the longline fishery

(1987–89) troll and handline CPUE declined (Boggs[3]). However, troll CPUE returned to a typical level in 1990 and handline CPUE reached a high level in 1991 (Fig. 4B) despite continued high levels of fishing by all three pelagic fisheries. Thus availability (CPUE) of yellowfin tuna in Hawaii did not appear to be closely related to changes in local fishing pressure.

Local availability of yellowfin tuna seemed to follow patterns in the overall abundance or catchability of the stock as indicated by CPUE in wide-ranging Japanese longline and purse seine fisheries. Standardized yellowfin tuna CPUE in the longline fishery of Japan in the western Pacific from 1952 to 1986 (Suzuki, In press) indicated a drop in CPUE between the 1950's and early 1960's, and a decline in the early 1980's (Fig. 4C) similar to that seen in Hawaii longline CPUE data (Fig. 4A). In more recent years (1983–88), Hawaii troll CPUE followed a pattern that was similar to Japanese western Pacific purse-seine CPUE (Suzuki, In press; Boggs, In press; Skillman et al., 1993). Environmental anomalies affecting catchability may contribute much of the corresponding variation seen in CPUE time series, such as the peak in yellowfin tuna CPUE that occurred in 1978 (Fig. 4A and 4B).

An initial increase in bigeye tuna CPUE in the early years of the Hawaii fishery (Fig. 5A) was explained by Shomura (1959) as the result of a change in the area fished during winter as fishermen learned to target bigeye tuna. Set depth also changed between the late 1940's and early 1950's as the practice of buoying up the middle of each basket of gear with an extra float (June, 1950) was abandoned. Deep gear has been shown to be more efficient than shallow gear in catching bigeye tuna (Hanamoto, 1976; Suzuki et al., 1977; Boggs, 1992).

Bigeye tuna CPUE in the Hawaii longline fishery (Fig. 5A) and in the wide-ranging Japanese longline fishery (Fig. 5B) (Miyabe, In press) both showed downward trends from the late 1950's through the 1960's, a distinct drop in CPUE in 1970, a stable period in the mid-1970's, record low levels in 1980–81, and a slight recovery in the mid 1980's. The correspondence between the bigeye tuna CPUE statistics for the entire Pacific and for Hawaii is remarkable, and strongly suggests that local pelagic fish availability is linked to the abundance of a widespread population. An alternative hypothesis that could apply to all of the pelagic species is that CPUE variation is due to widespread changes in catchability associated with environmental trends.

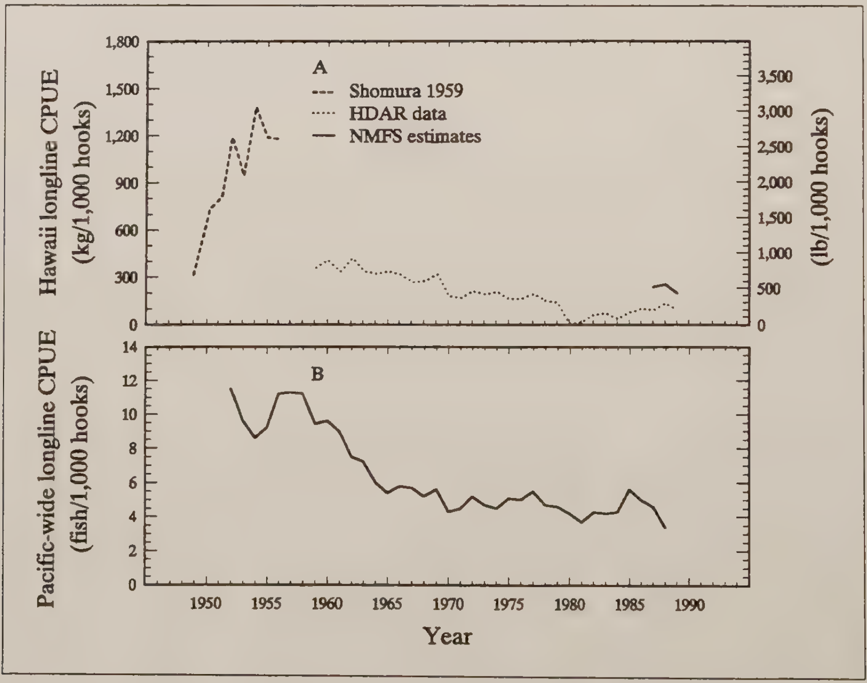

Figure 5.— Bigeye tuna CPUE time-series showing A) Hawaii longline CPUE (in kg and lb per 1,000 hooks) from 1949 to 1956 (fiscal years ending in June, Shomura, 1959), 1959–89 (HDAR data), and 1987–89 (NMFS estimates), and B) Pacific-wide longline CPUE (in no. fish per 1,000 hooks) in the Japanese fishery from 1952 to 1987 (Miyabe, In press).

For bigeye tuna, the Hawaii longline CPUE continued to recover in the late 1980's (Fig. 5A), whereas Japanese CPUE declined (Fig. 5B). The increasing trend in Hawaii bigeye tuna CPUE in the 1980's brought the CPUE index based on NMFS wholesale market sample back up to a level slightly higher than the average for 1970–78 (Fig. 5A) suggesting that local longline fishery expansion in the 1980's did not negatively affect bigeye tuna availability.

The blue marlin CPUE time series for the Hawaii longline fishery (Fig. 6A) showed peaks and minima for the same years as the Hawaii troll CPUE time series (Fig. 6B). The close correspondence between blue marlin CPUE in these two fisheries suggests that both CPUE time series reflected true changes in availability or catchability despite the limitations of the available statistics.

Blue marlin (Fig. 6A) and striped marlin (Fig. 7A) CPUE in the Hawaii longline fishery followed a pattern similar to Japanese longline CPUE data (Fig. 6C and 7B), as noted by Wetherall and Yong[16] and Skillman and Kamer[4]. This correspondence was not limited to the long-term decline in CPUE characteristic of longline fisheries in all oceans. Rather, for striped marlin both increases and decreases in CPUE in the Hawaii longline fishery (Fig. 7A) corresponded with CPUE changes in the North Pacific Japanese longline fishery (Fig. 7B).

The sharp increase in longline CPUE for blue and striped marlin in 1989 probably reflected the increased use of monofilament longline gear without

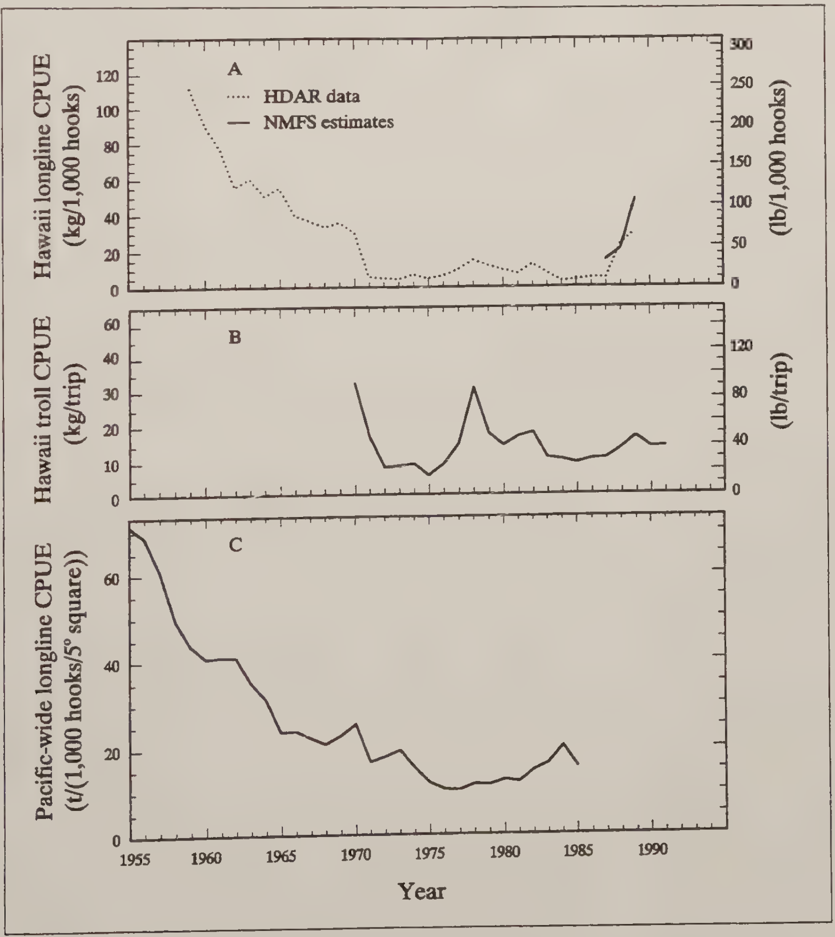

Figure 6.— Blue marlin CPUE time-series showing A) Hawaii longline CPUE (kg and lb per 1,000 hooks) from 1959 to 1989 (HDAR data), and 1987–89 (NMFS estimates), B) Hawaii troll CPUE (in kg and lb per trip) from 1970 to 1991 (HDAR data), and C) Pacific-wide longline CPUE (in t per 1,000 hooks per 5° square) in the Japanese fishery from 1955 to 1985 (Suzuki, 1989).

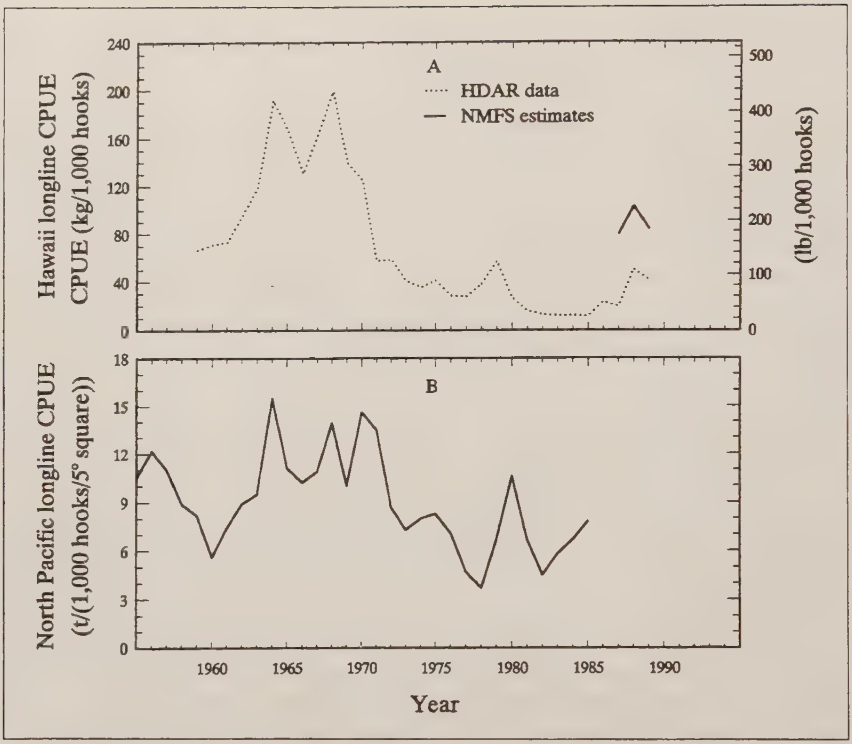

Figure 7.— Striped marlin CPUE time series showing A) Hawaii longline CPUE (in kg and lb per 1,000 hooks) from 1959 to 1989 (HDAR data), and 1987–89 (NMFS estimates), and B) North Pacific longline CPUE (in t per 1,000 hooks per 5° square) in the Japanese fishery from 1955 to 1985 (Suzuki, 1989).

line-throwers, which resulted in shallower sets and increased the efficiency of the gear for marlin (Suzuki, 1989; Boggs, 1992). Blue marlin CPUE in the troll fishery appears to be at a normal level and relatively stable (Fig. 6B) despite the expansion of Hawaii's pelagic fisheries.

Mahimahi CPUE in the Hawaii longline fishery (Fig. 8A) reached a peak in 1972 and a minimum in 1988 that were mirrored in the Hawaii troll and handline CPUE data (Fig. 8B). Troll and handline CPUE data corresponded with each other very closely. Mahimahi CPUE appears to be increasing in both the troll and handline fisheries.

## Outlook for the Pelagic Fisheries

The absence of clear declining trends in local CPUE associated with local fishery expansion, combined with distinctly seasonal variations in CPUE (Shomura, 1959; Yoshida, 1974; Skillman and Kamer[4]), suggests that pelagic fish availability in Hawaii was most strongly affected by factors other than local fishing pressure. Anomalies in whatever factors control seasonal availability could also be the major source of interannual variation in CPUE. Research leading to an ability to forecast changes in pelagic fish availability could ameliorate fishermen's concerns that local fishing pressure has decreased fish availability. Development of new methods to locate or predict productive fishing areas could increase the yield and efficiency of Hawaii's pelagic fisheries. However, greatly increased fishing efficiency and yield might then have some negative impact on local fish availability.

Decreases in fish availability caused by local fishing pressure may have been obscured by biases such as increased fishing power, expansion into more productive fishing grounds, economic influences on fishing operations, and environmental influences on local abundance and catchability. Further analysis of catch and effort data as well as an improved data collection system are needed to attempt to account for such biases. However, the parsimonious explanation of the available data is that locally exploited stocks have not yet been impacted by the expansion of Hawaii's pelagic fisheries.

Long-term declines in the overall apparent abundance of many pelagic species occurred several decades ago (Figs. 4C, 5C, and 6C), before the latest (1970–91) expansion of Hawaii's pelagic fisheries. Pacific-wide declines in CPUE do seem to affect Hawaii's fisheries, and could reflect full exploitation or even overexploitation of the stocks. However, reduction of local

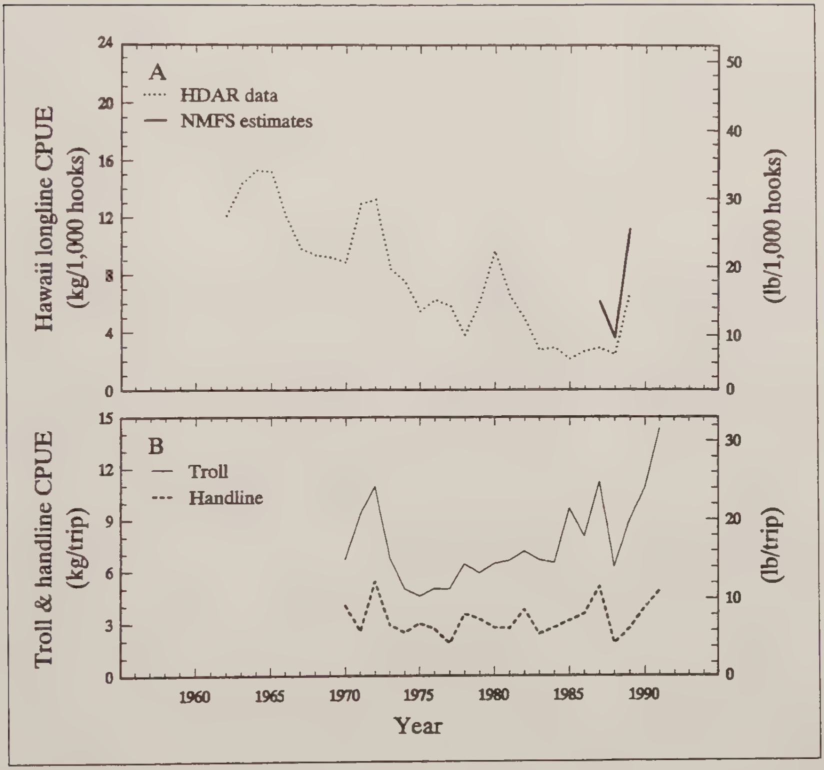

Figure 8.— Mahimahi CPUE time series showing (A) Hawaii longline CPUE (kg and lb per 1,000 hooks) from 1962 to 1989 (HDAR data), and 1987–89 (NMFS estimates), and (B) Hawaii troll and handline CPUE (in kg and lb per trip) from 1970 to 1991 (HDAR data).

fishing effort from current levels would not substantially affect stock-wide abundance because of the relatively small scale of Hawaii's pelagic fisheries. An exception might be the nighttime longline fishery for broadbill swordfish, which has been operating for too short a time to evaluate. However, with annual landings of 4,400 t and continued growth, the Hawaii swordfish fishery may be expected to contribute significantly to total fishing mortality on the stock. Historically, maximum total Pacific yields of swordfish have been on the order of 20,000 t per year (Bartoo and Coan, 1989).

If fishery managers can prevent physical conflicts between the longline and small-vessel troll and handline fisheries in Hawaii (Pooley, 1990; Skillman et al., 1993), and if adequate markets continue to support the profitable operation of all fishery sectors, then Hawaii's pelagic fisheries should continue to expand. No strong evidence suggests that the local availability of fish is a factor limiting further expansion. However, this optimistic assessment is based on statistics and analyses that may be inadequate; therefore, better fishery monitoring systems are needed.

## Acknowledgments

We thank Reggie Kokubun of HDAR for producing the data summaries for Hawaii's longline, troll, and handline fisheries for 1970–91. This paper is dedicated to Justin Rutka, longtime member of the WPRFMC's Pelagic Fishery Management Plan Team, in response to his unswerving quest to examine local pelagic CPUE time series.

# The Development and Decline of Hawaii's Skipjack Tuna Fishery

CHRISTOFER H. BOGGS and BERT S. KIKKAWA

*ABSTRACT—The pole-and-line fishery for skipjack tuna,* Katsuwonus pelamis, *was the largest commercial fishery in Hawaii until its decline in the 1970's and 1980's. The development and decline of the fishery were strongly affected by fish availability and marketing. A sustained drop in the availability of large fish in the mid-1970's appears to have been due in part to a sustained environmental change. Availability of large fish subsequently increased, but the fishery continued its decline owing to low profitability and lack of markets. The tuna cannery in Honolulu that fostered the fishery's expansion in the 1930's closed in 1984. Unless efforts to increase the market for skipjack tuna become effective, landings will probably remain at current levels of about 1,000 metric tons per year. The existing pole-and-line fleet may continue to decline with age, and the local market may eventually be supplied by other fishing methods (e.g., trolling), by new vessels, or by imports.*

## Introduction

Historically, the pole-and-line, live-bait fishery for skipjack tuna, *Katsuwonus pelamis*, was the largest commercial fishery in Hawaii. Annual pole-and-line landings of skipjack tuna exceeded 2,500 metric tons (t) or 5.5 million lb from 1937 to 1973 (June, 1951; Yamashita, 1958; Uchida, 1976; Skillman, 1987; Kikkawa[1]), except during World War II (1941–45). The record production of 7,400 t (16.3 million lb) of all species landed in 1965 by the pole-and-line fishery was unsurpassed until 1991, when the Hawaii longline fishery landed 8,000 t (all species combined). Even so, at its largest, the Hawaii skipjack tuna catch was small compared with the total Pacific catch of this species (ca. 870,000 t in 1990; IATTC, 1992; Hampton, In press).

The Hawaii skipjack tuna fishery originally supplied only the local market for fresh and dried tuna. The fishery expanded in the 1900's because the ready availability of skipjack tuna was sufficient to support a cannery which provided access to outside markets. A sustained drop in the catch per unit effort (CPUE) of large (>6.8 kg, >15 lb) skipjack tuna began in 1974. The decrease in CPUE was related to environmental changes affecting local fish availability (Mendelssohn[2]; Boggs, 1988). Combined with increased fishing costs, market competition from other tuna products, and the 1984 closure of the Hawaiian Tuna Packers, Ltd. cannery in Honolulu, these factors caused a major decline in Hawaii's skipjack tuna fishery during the late 1970's and 1980's (Boggs and Pooley, 1987; Hudgins and Pooley, 1987). The fishery has not recovered.

Expanding fisheries for skipjack tuna throughout the Pacific (Forsbergh, 1980; IATTC, 1992; Hampton, In press) do not appear to have caused the decline in Hawaii's fishery (Boggs and Pooley, 1987; Kearney, 1987; Sibert, 1987), although further analyses may reveal negative impacts. Skipjack tuna are relatively impervious to overfishing (Boggs and Pooley, 1987; Hampton, In press) due to widespread distribution and reproduction, rapid growth, early maturity (Matsumoto et al., 1984), and frequent spawning (Hunter et al., 1986). Unlike populations of larger tuna species (Miyabe, In press; Suzuki, In press) and marlins (Suzuki, 1989), skipjack tuna appear to be underexploited (Kleiber et al., 1983; Hampton, In press). The absence of regulation in Hawaii's skipjack tuna fishery contrasts with the management of Hawaii's fisheries for other tunas and billfish (Boggs and Ito, 1993), and is justified by the apparent underexploitation of the stock and the declining size of the local fishery.

This review describes the Hawaii skipjack tuna fishery, its development through the 1970's, and subsequent decline. Research on factors contributing to the decline are summarized and the fishery community's attempts at revitalization are described.

## Description and Historical Development

In Hawaii, skipjack tuna, commonly called by its Hawaiian name "aku," is mostly caught by pole-and-line fishing (e.g., >99% through 1974, 72% in 1990). This method uses live bait thrown from a fishing vessel to stimulate a surface school into a feeding frenzy. Fishing is then conducted frantically to take advantage of the limited time the school remains near the boat. The pole and line are of equal length (ca. 3 m) and are used with a barbless hook with feather skirts which is slapped against the water until a fish strikes. Then the fish is yanked into the vessel in one motion. The fish unhooks when the line is slacked so that the process can be repeated.

The bait most often used is the anchovy *Encrasicholina purpureas*, commonly called by its Hawaiian name "nehu." Each fishing vessel seines for bait in bays, harbors, and other sheltered waters, and the bait is not "hardened" for long-term transport or for use more than a few days after capture. The fishery is limited to areas close to the eight main Hawaiian Islands. Skipjack tuna are located by searching for bird flocks associated with surface schools. Fishing trips seldom last longer than a day, and most vessels return to port each night.

The basic pole-and-line method in use today was practiced in the 1800's largely by native Hawaiians using canoes (June, 1951). In 1900 the fishery was relatively small, with total landings of 190 t (0.4 million lb, Fig. 1) sold in the fresh market (Yamashita, 1958). Around the turn of the century Japanese immigrants began introducing small (ca. 6 m) shallow-draft wooden sampans with built-in bait wells, followed by motor powered vessels starting in 1907. In the 1930's the vessels were redesigned to be larger, with deeper draft, flying bridges, pump-spray systems, and greater freeboard forward to give them better seaworthiness (June, 1951). Pump-spray systems agitate the water around the vessels during fishing. To the fish, the agitated water may resemble a school of bait and partly obscure the view of the boat and fishermen.

The Hawaiian Tuna Packers, Ltd. cannery in Honolulu was established in 1917, enabling the fishery to expand beyond a relatively small fresh and dried market. The greatest annual amount sold in the fresh and dried market was 2,200 t (4.9 million lb) in fiscal year 1935 (i.e., July 1934–June 1935, Yamashita, 1958). The market for canned product allowed the fishery to expand to a peak of 6,100 t (13.4 million lb) in 1940 (Fig. 1) followed by a hiatus during WWII. From 1937 until the early 1980's most of the skipjack tuna landed in Hawaii was canned.

Before WWII the fishery included up to 26 vessels (Hudgins and Pooley, 1987) and landed an average of 5,000 t (2.3 million lb) per year from 1937 to 1940. Most vessels constructed before WWII averaged about 31 t displacement and had a bait-well capacity below 3,000 L (800 gallons, defined as Class I vessels). Larger sampans, averaging 58 t, were mostly built in the late 1940's and 1950's. These generally had a bait-well capacity greater than 3,000 L (defined as Class II vessels, Uchida, 1976; Kikkawa[1]).

As new vessels were built, fleet size increased to a maximum of 32 vessels in 1948. The prewar landings record was surpassed in 1954 (Fig. 1). During the 1950's through the early 1970's the fleet landed an average of about 4,000 t per year. Interannual variation in catch was large, but no significant long-term trend was apparent from 1948 to 1970 (Uchida, 1976).

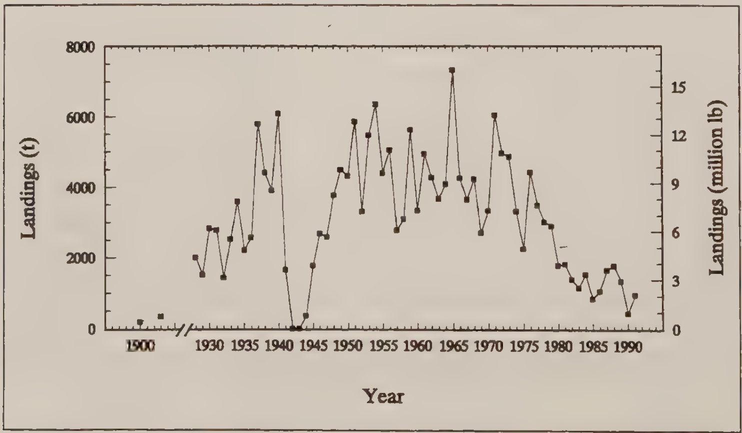

Figure 1.— Total annual skipjack tuna landings in metric tons (t) and pounds (lb) by the pole-and-line fishery in Hawaii, 1900–91. Sources: 1900–47 from Yamashita (1958); 1948–70 from Uchida (1976); 1970–83 from Kikkawa[1], 1984–85 from State of Hawaii Division of Aquatic Resources; 1986–87 from Pooley[4], and 1988–91 from Ito[3].

Total catch levels remained high despite a decline in fleet size from 32 to 15 vessels between 1948 and 1971 because 1) fishing efficiency increased as the proportion of Class II vessels in the fleet increased, and 2) the number of days fished per boat increased (Uchida, 1976). As a result, total standardized effort in the 1970's averaged only slightly below that in the 1950's (Uchida, 1976; Skillman, 1987; Kikkawa[1]) (Fig. 2).

From the 1970's to the present most of the active vessels have been the remaining wooden-hulled sampans built in the 1940's and 1950's. These vessels carry crews of 7–9 fishermen, and frequently work 6 days a week. The work is arduous and may begin with bait seining at dawn followed by fishing to dusk. One new steel-hulled vessel with about twice the displacement (91 t) of the old wooden vessels entered the fishery in the 1970's, but was not very successful.

## The Decline

Since the mid-1970's the trend in Hawaii skipjack tuna landings has been downward (Fig. 1), reflecting both a decline in fishing effort (Fig. 2) and CPUE (Fig. 3). Current (1990–91) annual landings average <1,000 t (2.2 million lb) (Ito[3]). By the mid 1980's the number of vessels in the fishery had fallen to nine (from 15 in 1971) and in 1991 only six vessels were active, four active on a full-time basis. Fishing effort dropped after 1979, falling to 1,023 Class II fishing days in 1981 and 922 days in 1986 (Fig. 2). Another major drop in fishing effort occurred in 1989–90 (Ito[3]) and 1991 effort was only 553 fishing days (Fig. 2). Fishing effort data for 1948–83

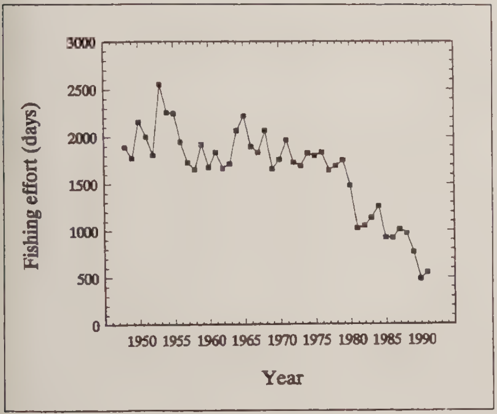

Figure 2.— Total annual fishing effort (in days) by the pole-and-line fishery in Hawaii, 1948–91. Effort data for 1948–83 and 1986–87 are standardized (Uchida, 1976; Kikkawa[1]). Sources as given in Figure 1.

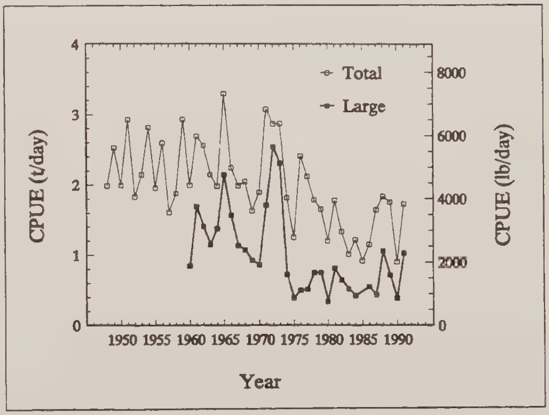

Figure 3.— Annual skipjack tuna CPUE in metric tons (t) and pounds (lb) per vessel per day for all sizes (total) and large fish (>6.8 kg or 15 lb), 1948–91. Sources as given in Figures 1 and 4.

(Uchida, 1976; Kikkawa[1]) and for 1986–87 (Pooley[4]) were standardized (Fig. 2) to account for zero-catch trips and relative efficiency (Class I versus Class II). Data for 1984–85 and 1988–91 were summary statistics without the information required for standardization. The importance of standardization was minimal after 1987 because the 1988–91 data included zero-catch trips and contained primarily Class II fishing days.

Catch rates (CPUE in t/Class II fishing day) exhibited a declining trend in the 1970's and 1980's (Fig. 3). The high degree of interannual variability in CPUE was typical of geographically restricted surface fisheries for skipjack tuna, but the declining trend was unusual. In particular, the drop in CPUE for large (>6.8 kg, >15 lb) skipjack tuna in 1974 was extreme and was sustained though 1987 (Fig. 3).

Large (>6.8 kg) skipjack tuna historically represented over 50% of the Hawaii landings by weight (Fig. 4). None of the world's major skipjack tuna fisheries depend on such large fish to supply the bulk of their catch. Large skipjack tuna command higher prices in both the fresh fish and cannery markets. From a high of over 80% in 1972–73 the proportion of large fish in Hawaii landings fell to a low of 40% in 1974 and remained below 40% through 1977 (Fig. 4). Reduced landings of large fish resulted in a substantial decrease in profitability to the pole-and-line fishery (Hudgins, 1987). The proportion of large fish in the catch has shown an upward trend since 1977 but has only exceeded 50% in a few years (1983, 1988, and 1991, Fig. 4).

The distribution of fishing effort by the fleet also changed in the 1970's. At the height of the fishery in the 1950's and 1960's, several vessels were based on the islands of Hawaii and Maui, and sizable catches came from the northeast coasts of these islands (Uchida, 1970). In the 1970's and 1980's most of the catch came from areas around Oahu, Kauai, Molokai, and Lanai (Kikkawa[1]). Presently all of the vessels work out of Kewalo Basin or Kaneohe Bay on Oahu.

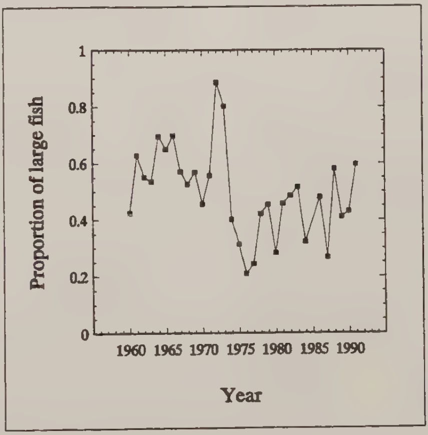

Figure 4.— The proportion of large (>6.8 kg or 15 lb) fish in annual skipjack tuna landings by the pole-and-line fishery in Hawaii, 1960–91. Sources for size composition of catches: 1960–84 and 1986–87 from Pooley[4] and 1988–91 from Ito[3].

Increasing age of the fishing fleet and rising fuel prices may have contributed to more conservative fishing practices in the 1970's and 1980's, resulting in fewer trips taken far from land. In the 1970's skipjack tuna pole-and-line vessels also began to fish around fish aggregating devices (FAD's), in addition to the more traditional practice of scouting for bird flocks to locate fish. If large skipjack tuna were more common farther offshore, a greater frequency of nearshore trips might have contributed to the decreased catch of large fish. Uchida and Sumida (1971) found the average size of skipjack tuna caught by 7 vessels in the summer of 1967 was smallest in areas closest to Oahu.

Changes in the geographic distribution of fishing effort in the 1970's appear to have affected overall CPUE, which was consistently higher than average for oceanic areas, defined as more than 37 km (20 n.mi.) from shore (Uchida, 1966, 1970, 1976). The catch from oceanic areas averaged about 25% of the total catch from the 1950's through the early 1960's (Uchida, 1966). From 1974 to 80 catches from oceanic areas averaged only about 20% of the total catch (Kikkawa[1]). Data on the distribution of the catch in more recent years have not been summarized.

The cannery closed in 1984 because of economic restructuring in the global tuna industry and because of market constraints (King, 1987). The decline in Hawaii skipjack tuna landings contributed to the problems of the cannery but was not directly responsible for its closure. This pivotal event left the fishery with only a local, fresh and dried fish market. Previously, the fishery had been highly seasonal; summer (May–September) landings averaged about 400 t (900,000 lb) per month accounting for about 70% of annual landings (1964–82 average, Hudgins[5]). However, the fresh fish market absorbed only about 140–200 t (300,000–450,000 lb) per month after the cannery closed, reducing summer landings to about 54% of annual landings (1986–87 average, Pooley et al.[6]).

The decline of the Hawaiian domestic pole-and-line fishery roughly coincided with increases in skipjack tuna landings by the domestic troll fishery in Hawaii. The amount of skipjack tuna caught by domestic longline and handline fisheries in the Hawaii Exclusive Economic Zone (EEZ) has always been relatively insubstantial, but commercial troll catches increased from <1% of Hawaii's total skipjack tuna landings in the early 1970's to 10% in 1985 and to about 20% in 1990 and 1991. Expressed as a percentage, this increase is partly due to the decline in pole-and-line landings, but troll landings did increase from <50 t (<0.1 million pounds) in the early 1970's to >200 t (>0.5 million pounds) in 1991 (Boggs and Ito, 1993).

Pole-and-line vessels from Japan fishing for skipjack tuna within the EEZ surrounding the Northwestern Hawaiian Islands also increased their catches during the decline of Hawaii's domestic pole-and-line fishery. Foreign fishing effort increased from 213 to 767 vessel-days from 1972 to 1977, while foreign catch increased from 1,000 to 4,600 t (Yong and Wetherall, 1980). From 1978 to 1984 the annual catch in the EEZ by the foreign fishery ranged from 2,000 to 4,000 t, reaching twice the level of the domestic catch (Boggs, 1987). No foreign data have been obtained since 1984, but this fishery continued to operate legally in the EEZ through 1992. New regulations may discourage the continuation of this fishery in 1993.

## Causes for the Decline

### Bait Problems

A lack of bait during certain times of the year is frequently cited as a problem by Hawaii fishermen. The CPUE (catch per trip) for bait fish in the 1970–81 period (Kikkawa[1]) averaged slightly (ca. 4%) higher than in the previous decade (Uchida, 1977) but showed a declining trend. In 1986–88, bait fish CPUE in Pearl Harbor averaged 27% lower than that in 1970–81 (Kobayashi[7]). These modest declines (1970–81, 1981–86) in bait fish CPUE may have contributed to the problems of the pole-and-line fishery but were not viewed by industry participants as a direct cause for the decline of the fishery (Boggs and Pooley[8], 1987).

A more serious problem for some vessels has been the high cost of the vessel insurance required for entering U.S. military areas (i.e., Pearl Harbor) to catch bait (Boggs and Pooley[8], 1987). Alternatives to the harvest of wild bait by each individual vessel have been proposed (Shug and Shang[9]), but Hawaii fishermen are very resistant to purchasing bait, especially when wild bait is available. Under present conditions, the rearing or importation of bait fish would be stop-gap measures and would not be economically feasible (Shug and Shang[9]).

### Fish Availability

Owing to the small scale of Hawaii's skipjack tuna fishery, local fishing pressure is not likely to affect the availability of skipjack tuna in Hawaii. Uchida (1976) showed that in Hawaii, changes in CPUE were not associated with changes in local fishing intensity at a time when the local catch was much higher than it has been in recent years. The increase in pole-and-line catches by foreign vessels in the Hawaii EEZ in the 1970's roughly coincided with the decline of Hawaii's pole-and-line fishery (Boggs, 1987), but there was no significant correlation between annual catch by the foreign fishery in the EEZ and domestic CPUE ($r = -0.34$, $p > 0.25$, $N = 13$) for years with available data (1972–84).

More research is needed to establish whether the Pacific-wide increase in catch from <500,000 t in 1980 to almost 900,000 t in 1990 (IATTC, 1992; Hampton, In press) has affected the availability of skipjack tuna to Hawaii fishermen. The evidence suggests major increases in catch have had no effect on relative abundance, as indicated by CPUE in large-scale fisheries. For example, the largest catch and the greatest increase in catch was in the western Pacific, where a doubling of the catch from 1980 to 1990 had no perceptible impact on CPUE in that region (Hampton, In press). Declining abundance might have been obscured by improvements in fishing efficiency that increase CPUE (Hampton, In press). However, tagging experiments in the western Pacific also suggest that skipjack tuna are too productive to be affected by current levels of harvest (i.e., <1 million t). Kleiber et al. (1983) estimated a western Pacific biomass of skipjack tuna on the order of 3 million t and a turnover rate of 6 million t/year. These studies (Kleiber et al., 1983; Hampton, In press) imply that the decline in Hawaii CPUE was not caused by a decline in the abundance of skipjack tuna in the western Pacific.

Some genetic evidence suggests that skipjack tuna in Hawaii are part of a central and eastern Pacific stock that is partially isolated from the western Pacific resource (Matsumoto et al., 1984; Kearney, 1987). Tagging experiments in the eastern Pacific have resulted in tag recoveries in Hawaii, whereas western Pacific tagging experiments have not (Kearney, 1987). Therefore, the decline in Hawaii's CPUE (Fig 4) might logically be attributed to a corresponding increase in eastern Pacific skipjack tuna catches (Hudgins[5], 1987) which exceeded previous (1960–74) levels in 1975 and remained higher than average through 1982 (IATTC, 1992). However, the timing of this increase could not correctly explain the decline in catches in Hawaii a year before (in 1974). Moreover, eastern Pacific catches subsequently declined (1983–90, IATTC, 1992) without a corresponding increase in Hawaii's CPUE (Kearney, 1987). Furthermore, CPUE in the eastern Pacific seems to be unaffected by harvest level (IATTC, 1992).

If there was a negative impact of the eastern Pacific fishery on Hawaii's fishery, it would most likely take effect after a time lag to give eastern Pacific fish time to reach Hawaii and to grow to the size harvested by Hawaii's fishery (Kearney, 1987). A significant ($r = 0.54$, $p < 0.05$, $N = 30$ years) negative correlation has been found between the Hawaii catch of skipjack tuna and the total catch (of all sizes) in the eastern Pacific one year earlier (Ianelli[10]). However, a better indicator of interaction between these fisheries would be a significant negative correlation between CPUE (rather than catch) in Hawaii and the eastern Pacific catch in the preceding year. No such correlation has been found (Kearney, 1987; Ianelli[10]).

The unusual dependence of Hawaii's skipjack tuna fishery on large fish means that it is more sensitive to changes in fish population size structure than the large-scale fisheries of the eastern and western Pacific. A reduced size-frequency distribution of the population due to increasing harvests by large-scale fisheries might not be reflected in the CPUE of those fisheries but still affect availability of large skipjack tuna in Hawaii (Boggs, 1987). Eastern Pacific skipjack tuna size-frequency distributions show decreasing average size from 1972 to 1981 followed by increasing average size through 1985 (IATTC, 1985, 1992). This sequence does not correspond closely with Hawaii's abruptly reduced proportion of large fish in 1974, or the increasing trend after 1977 (Fig. 4). Further analyses of these data are being conducted (Ianelli[10]). In the western Pacific, improved collection and analysis of size-frequency data are needed for evaluation of fishery interaction (Hampton, In press).

Annual time series of skipjack tuna catch in Hawaii have been found to be correlated with sea surface temperature (Jones[11]) and salinity (Seckel, 1972). Various models have been used to predict annual catches based on these environmental variables (Mendelssohn[2]; Boggs, 1988, 1989). The most recent model based on sea surface temperature (Boggs, 1988) explained 68% of the variation in the CPUE of large skipjack tuna during 1960–83 (Fig. 5). This model suggests that a sustained decline in CPUE for large skipjack tuna after 1973 was related to a sustained change in spring sea surface warming patterns east of Hawaii.

Spring warming patterns reflect the relative strength and northward extent of the California current extension (CCE) which joins the North Equatorial Current (NEC) near Hawaii. An hypothesis is that the CCE and NEC provide a conduit for immigration of large skipjack tuna from the eastern tropical Pacific to Hawaii (Seckel, 1972; Boggs, 1988). The most recent models also involve a time lag (Mendelssohn[2]; Boggs, 1988) which could reflect relationships between temperature and recruitment, mortality, or migration in preceding years. Previous models (e.g., Seckel, 1972) explained variation in Hawaii CPUE based on the proximity of the north edge of the CCE or NEC as measured by sea surface temperature and salinity in Hawaii, but these models eventually failed to provide good predictions when the north edge of the current passed north of the islands (Skillman[12]).

The spring warming model (Mendelssohn[2]; Boggs, 1988) was used to predict CPUE for large skipjack tuna during 1984–90 and indicated that the availability of large skipjack tuna

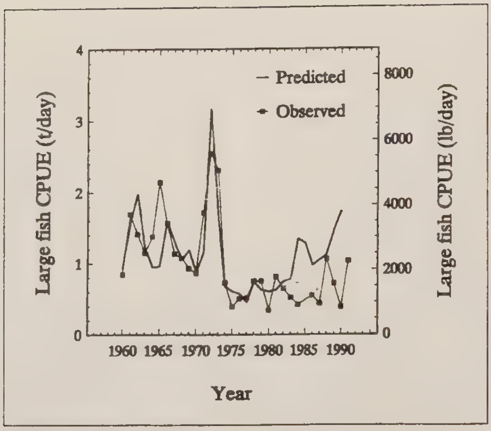

Figure 5.— Annual skipjack tuna CPUE in metric tons (t) and pounds (lb) per vessel per day for large fish (>6.8 kg or 15 lb), 1960–91, compared with CPUE predicted by an environmental model. Sources as given in Figures 1 and 4.

around Hawaii should have returned to pre-1974 levels after 1983 (Fig. 5). Although the proportion of large fish in the Hawaii catch returned to 1960–73 average levels in 1988 and 1991 (Fig. 4), the CPUE for large skipjack tuna in recent years has remained much lower than predicted (Fig. 5).

Three factors that may have contributed to lower-than-predicted CPUE after 1983 were 1) a self-imposed quota employed by vessels to avoid flooding a limited market, 2) reduced scouting and fishing closer to port, and 3) a change in the overall age structure of the population because of increased fishing pressure elsewhere in the Pacific. The first two factors are economic, and could result in reduced CPUE without any change in fish abundance. For example, CPUE is biased downwards by a self-imposed quota (factor 1) because measures of effort (days) and CPUE (catch per day) do not account for trips of less than a day when a quota is achieved early in the day. Increased fishing near shore (factor 2) would decrease CPUE because average CPUE is highest >37 km from shore (Uchida, 1966, 1970, 1976) and fish may be smaller than average near shore (Uchida and Sumida, 1971). Existing analyses do not indicate that the availability of large fish has been reduced by the impacts of fishing on population age structure (factor 3) but further study is needed.

## Economic Causes of the Decline

One economic factor in the continuing decline in total catches after 1974 (Fig. 1) was a negative correlation between catch and the price of fuel (Hudgins[5]). In a comparison of catches for 1982 with those for 1974, the decrease in annual catch attributable to fuel price increases was estimated to have reduced annual revenue by $1.3 million. Over this same period, a decrease in catch attributable to reduced CPUE and a low proportion of large fish in the catch (Fig. 4) were estimated to have reduced annual revenue by $1.0 and $0.36 million, respectively (Hudgins[5]). These losses represent over 50% of potential revenue; actual revenue was only $2.5 million in 1982 (Pooley et al.[6]).

The mechanism by which fuel price increases affect the catch has not been documented, but the fuel price rise that began in 1973 did not immediately affect the total number of fishing days (Fig. 2). Perhaps expensive fuel and poor maintenance on some vessels result in restricted scouting for schools of fish and in fishing closer to land. Fishing around FAD's may increase the proportion of small fish in the catch (Boggs and Pooley, 1987), but FAD fishing seems to be mostly a last resort when schools of larger fish cannot be located. Small fish landings increased in 1976 whereas FAD's were not fully deployed until 1980 (Hudgins[5], 1987).

Declining profitability has played an important role in the decline of the fishery (Pooley, 1987). Low earnings since the 1960's curtailed investment in new boats. Attempts to increase profits by selling more high-priced, fresh skipjack tuna faced market limitations even before the cannery closed. During 1970–85 the price per ton rose 45%, but costs rose 75% (after inflation). To offset fuel (200%) and insurance (390%) cost increases, the share of profit paid to crews was kept low, and repairs were postponed (Pooley, 1987). Poor maintenance resulted in frequent breakdowns and safety problems. Five vessels which sank during the 1980's and 1990's have not been replaced. Such problems may have influenced the fleet's fishing range, resulting in fewer fishing trips to more productive oceanic areas. Now, most of the vessels still remaining in the fleet are well maintained.

An increase in troll, handline, and longline landings of yellowfin and bigeye tunas during the 1970's and 1980's resulted in competition for the fresh tuna market, reducing the available market for skipjack tuna after the cannery closed. Although skipjack tuna is priced lower than yellowfin tuna (on average) and is appreciated by Hawaii residents in raw, cooked, and dried product forms, it is not widely accepted in the local restaurant (tourist) or export markets. In 1985 the average ex-vessel price for skipjack tuna was only $2.48/kg ($1.13/lb), whereas the average price for yellowfin tuna was 26% higher. The price difference has increased along with prices, and in 1991 the average yellowfin tuna price of $4.98/kg ($2.26/lb) was 58% higher than the average skipjack tuna price. Yellowfin tuna can readily be sold to the restaurant market in Hawaii or exported, and it has a much longer shelf life than skipjack tuna. Yellowfin and bigeye tuna are preferred over skipjack tuna for sashimi in the export markets. Flash-frozen skipjack and yellowfin tuna imported to Hawaii from Japan also competes with the Hawaii fishery for a share of the local market. The flash-frozen product is acceptable for sashimi, although it can be distinguished from fresh skipjack tuna.

The closure of the Honolulu tuna cannery in 1984 cost the skipjack tuna fishery an estimated $0.5 million (18%) in annual sales, and the loss would have been much worse had the fishery not already been so reduced (Hudgins, 1987). The most pronounced effect of the closure has been to discourage revitalization of the fishery. The lack of a cannery market is especially troublesome during the summer when the skipjack and yellowfin tuna fisheries reach peak production. As a result, pole-and-line vessels occasionally experienced severe market competition and devastating price reductions in the 1980's (Boggs and Pooley, 1987).

Self-imposed catch limits are now employed by Hawaii pole-and-line vessels to avoid flooding the limited fresh-fish market, especially on trips made during summer when fish are most available (Boggs, 1988, 1989). Incorporation of a monthly limit to landings with an environmental model (Boggs, 1988) produced more realistic predictions of CPUE and annual catch (Boggs, 1988, 1989). Since summer is also the season when large fish predominate in the catch, self-imposed quotas contribute to a lower proportion of large fish on an annual basis.

In summary, Hawaii's pole-and-line fishery was economically stressed throughout the 1970's and 1980's because of rising costs and reduced profitability (Pooley, 1987). Then from 1974–83 the availability of large fish declined because of environmental changes (Mendelssohn[2]; Boggs, 1988) and the fishery declined. Models based on environmental factors predict increased availability since 1983 but CPUE has remained low. Reasons for continuing low CPUE may include self-imposed quotas and fishing closer to shore than in the past. No clear evidence indicates that overfishing has had a negative impact in Hawaii or elsewhere in the Pacific. The fishery has not recovered owing to continued high costs, low profits, and a limited market.

### Remedies and Future Prospects

A workshop and a strategic planning process (Boggs and Pooley[8], 1987) were conducted in Honolulu in 1986 to discuss causes of the fisheries decline and remedial actions. An expanded market and products with a long shelf life to absorb peak production during the summer were seen as the most important objectives for revitalizing the fishery. A group of investors purchased the cannery facility in 1985 with the intention of integrating it into a marine-oriented tourist center but the cannery has not reopened. Making tuna canning profitable in Hawaii would require promotion of specialty packs that appeal to tourists and local residents, because production of normal canned tuna in Hawaii is too expensive to compete on the world market (King, 1987).

The available evidence indicates that the skipjack tuna population can easily support an expanded fishery in Hawaii, although the fishery would remain vulnerable to an environmentally driven reduction in availability like that of 1974–83. If ocean-wide fishing pressure has had an impact on availability, local (EEZ) management would not substantially ameliorate that impact because the local fishery is relatively small. Bait fish stocks would be the only resources that might require local management if the fishery were to expand. These stocks were sufficient in the 1970's to support three times the number of full-time vessels currently active. The modest decline of bait fish stocks (ca. 27%) since the 1970's might become a limiting factor if the fishery were to more than double its present size. If the profitability of the fishery increased, it might be able to support a bait fish culture industry (Shug and Shang[9]).

The future of the fishery depends primarily on the development of markets. The State of Hawaii has conducted market expansion projects and supported experiments to try and increase product shelf life, but these have not been very successful, in comparison with similar efforts in promoting other species. Expansion of the market will likely require innovative product technology that can economically preserve summer catches for later sale or fishing technology that will permit increased catches during the season of low availability.

In 1986 Hudgins (1987) predicted that without new markets, economic competition would force all but 4 or 5 of the most efficient Hawaii skipjack tuna fishing vessels out of business. She predicted that these vessels would supply about 900 t (2 million lb) of the skipjack tuna in the Hawaii fresh market at prices of $2.75–3.85 per kg ($1.25–1.75/lb). These predictions are almost exactly met by the number of vessels (6, 4 full-time), landings (955 t, 2.1 million lb), and average price ($2.87/kg, $1.30/lb) for skipjack tuna in 1991. Unless a larger market is developed, there is no reason to expect much expansion of Hawaii's skipjack tuna fishery in the near future. The pole-and-line fleet may continue to decline with age and the local market may increasingly be supplied by imports and by Hawaii's commercial troll fishery.

### Acknowledgments

We thank Shoji Teramoto and Russell Ito of the NMFS Honolulu Laboratory for collecting the data on catch, number of trips, and size composition of the catch for 1986–91. We also thank Sam Pooley, Richard Shomura, and Ray Sumida of the Honolulu Laboratory for helping to bring together the information needed for this review.

# Effects of entanglement and escape from high-seas driftnets on rates of natural mortality of North Pacific albacore, *Thunnus alalunga*

**Richard W. Brill**

North Pacific albacore (*Thunnus alalunga*) are heavily fished and may have experienced recent reductions in recruitment (NOAA, 1991). U.S. troll fishery landings and catch per unit of effort (CPUE) have been decreasing since the 1960's and are currently at only about 50% of their peak levels (Kleiber and Perrin, 1991; NOAA, 1991). Landings and CPUE by the Japanese pole-and-line fishery have also been falling continuously since the late 1970's[1]. North Pacific albacore are additionally targeted by longline fleets, and considerable numbers are taken by high-seas large- and small-mesh driftnet fleets. The small-mesh fleets of Japan, Taiwan, and Korea target neon flying squid (*Ommastrephes bartramii*) and incidentally capture albacore. The large-mesh fleets of Japan and Taiwan target albacore, skipjack tuna (*Katsuwonus pelamis*), and various billfishes (*Istiophoridae* and *Xiphiidae*).

Foreign driftnet fleets and U.S. trollers taking albacore overlap geographically (Fig. 1). They also target a common stock even when fishing in widely separated areas because of the trans-Pacific migration of albacore (Otsu and Uchida, 1963). Albacore that encounter drift nets, and escape to survive long enough to be recaptured by another fishery can bear some external marks[2,3]. These marks provide direct evidence of interactions among fisheries. U.S. trollers operating in the North Pacific have reported an increased frequency of net-marked fish with the expansion of the Taiwanese, Korean, and Japanese high-seas driftnet fleets (NOAA, 1991;[2,3]).

Albacore that become entangled in drift nets face a number of possible fates (Fig. 2). The fraction that become entangled and subsequently drop out (alive or dead) is not known. If it is significant, the North Pacific albacore stock could be affected more seriously by high-seas drift nets than landings alone indicate. Our study, part of a larger effort to determine the impacts of drift nets on the North Pacific albacore stock, was undertaken to determine whether albacore that encounter drift nets, and subsequently escape alive, suffer higher than normal rates of natural mortality.

Our strategy was to look for differences in measures of fitness, and differences in short-term and long-term growth rates between net-marked (i.e., fish that have encountered drift nets and escaped) and unmarked albacore. We also looked for indications of bacterial infection and long-term stress in net-marked albacore. These parameters could evince, although not quantify, differences in rates of natural mortality. We had to use indirect measures because rates of natural mortality (or physiological changes) could not be directly observed in albacore encountering simulated drift nets in shoreside tanks. Unlike skipjack and yellowfin tuna (*Thunnus albacares*) (Brill, 1992), albacore have yet to be successfully maintained in captivity.

Selection of specific parameters was constrained by the necessity of collecting measurements and samples at sea aboard small commercial fishing vessels. We could acquire only measurements and samples that could be obtained under difficult conditions and that did not interfere with normal fishing operations. We were further limited to collecting samples that could be stored for later processing in the laboratory and that would not reduce the market value of the catch. Given these constraints, we chose the following parameters. Weight to length and maximum girth to length ratios were used as indicators of general fitness (Bolger and

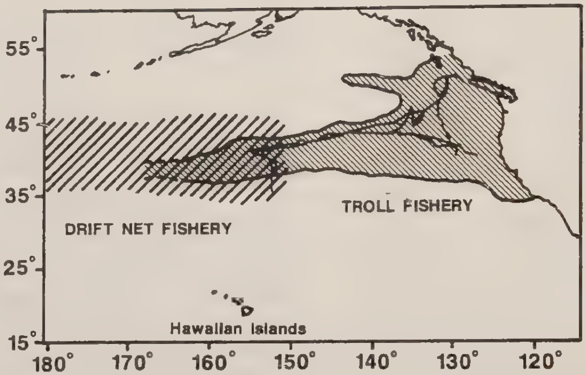

Figure 1

Area of operation of the U.S. troll fishery (light cross-hatching) catching albacore. Track lines of U.S. vessels carrying National Marine Fisheries Service observers in 1991 are shown by the solid line. Area of operation of foreign drift net fleets (heavy cross-hatching) extends west to approximately 140°W.

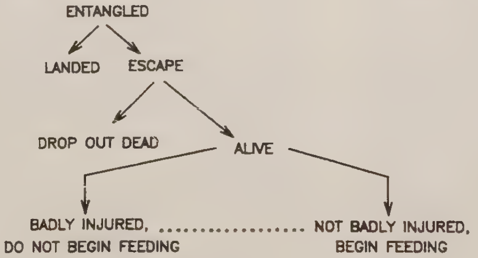

Figure 2

The possible fates of albacore that become entangled in high-seas drift nets. Note that the condition of fish which escape drift nets alive probably form a continuum from those that are so badly injured that they succumb quickly, to those that are only slightly injured and resume feeding immediately.

Connolly, 1989; Cone, 1989, 1990; Murphy et al., 1991). Relative otolith weight (i.e., the ratio of otolith weight to body weight) was used as an indicator of long-term growth rate (Boehlert, 1985; Pawson, 1990; Fletcher, 1991). (Because otolith weight is proportional to fish age rather than to body size, slower-growing fish have larger otoliths at a given body size because they have taken longer to reach that body size.) RNA:DNA ratio of white muscle was measured because it is an established indicator of short-term (days to weeks) growth rates (Bulow, 1970; Bulow et al., 1981; Ferguson and Danzmann, 1990; Mustafa et al., 1991). Relative leukocyte abundance (i.e., the ratio of leukocytes to red blood cells) was assessed as an indicator of bacterial infection and long term stress (Blaxhall, 1972; Anderson, 1990; Goede and Barton, 1990). Although muscle lipid content can be used as a measure of recent feeding history (Dotson, 1978), it was not used in this study. The lipid content of tuna muscle is dependent on sampling site (Dotson, 1978; Vileg et al., 1983; Boggs and Kitchell, 1991) and this factor could not be rigorously controlled.

## Materials and methods

During 1990 and 1991, observers were placed aboard ten U.S. trollers by the Southwest Fisheries Science Center (NMFS, NOAA), in cooperation with the Western Fishboat Owners Association. Observers documented the number of net-marked albacore landed and collected data and samples for our study. Boats operated in an area of the North Pacific shown in Figure 1. Albacore were classified according to the severity of net damage with a scheme (Table 1) developed by Bartoo et al.[2]. Fork length, maximum girth (both to the nearest centimeter), and body weight (to the nearest kilogram) were measured. Dried blood smears, sagittae (otoliths), and white-muscle samples (frozen in sealed tubes in the boats' commercial fish freezers) were also obtained from a subsample of landed fish selected by the observers. Muscle samples (taken from the small amount of muscle remaining near the skull following decapitation) and otoliths could be obtained only on vessels that processed (i.e., "gilled and gutted") their catches. Complete sets of samples were not, therefore, obtained from every fish.

In the laboratory, otoliths were dried, cleaned, and weighed to the nearest 0.1 mg on a Sartorius 1207 MP2 electronic balance. RNA and DNA were extracted from the frozen muscle samples by standard procedures (Hutchison and Munro, 1961; Munro and Fleck, 1966; Wilder and Stanley, 1983). The only modifications were that the RNA was extracted with 1.0 N NaOH, and the DNA with 1.2 N perchloric acid, both at 37°C for 60 minutes. RNA, DNA, and protein concentrations were measured with a Beckman model 35 UV spectrophotometer using the dual wave length method (Tsanev and Markov, 1960) and standard extinction coefficients (Wilder and Stanley, 1983). Red cells and leukocytes were counted in Geimsa-stained blood smears with the aid of light microscopy (oil immersion lens) in a minimum of three microscope fields, or until at least 200 red cells were counted. Eosinophils could be easily differentiated from the remainder

**Table 1**

Net damage classification scheme (Bartoo et al.[2]) used to assess severity of injury to albacore caused by entanglement and escape from drift nets, and the number fish in each damage code category examined for our study.

| Damage code | Damage description | Number of fish |
|---|---|---|
| 0 | No damage or scarring. | 217 |
| 1 | Minor damage along side(s) of fish, pattern of stripes due to minor scale loss where fish forced its way through or along the net. | 39 |
| 2 | Minor damage to head, chiefly forward of pectoral fins, brush-like pattern of scale loss. | 5 |
| 3 | Severe damage from bruising or scraping away of parts of the skin, primarily in area of greatest girth and mostly on dorsal surface. | 10 |
| 4 | Damage of any degree that was partially or completely healed. | 60 |

of the leukocyte population and were excluded from the total leukocyte count. Although Alexander et al. (1980) described the distinguishing features of albacore blood cells, we were only able to differentiate eosinophils clearly from the remainder of the leukocytes. Leukocytes were, therefore, not further classified.

By using data from unmarked fish only, regressions of body weight on fork length, maximum girth on fork length, and otolith weight on body weight were fitted by a least squares procedure (Statgraf Statistical Software) to the exponential equation:

$$Y = a \cdot x^b.$$

Regression parameters a and b were estimated for each case.

Relative condition factor, relative girth, and relative otolith weight for individual fish were then calculated with the regression parameters:

$$K = W/(a \cdot X^b).$$

When $K$ = relative condition factor, $W$ = body weight and $X$ = fork length; when $K$ = relative girth, $W$ = maximum girth and $X$ = fork length; and when $K$ = relative otolith weight, $W$ = otolith weight and $X$ = body weight.

Relative condition factor, relative girth, and relative otolith weight were calculated to permit direct comparison of groups containing individuals of different body sizes (Pollard, 1972; Brill et al., 1987).

The standard condition factor ($C$) was calculated separately for unmarked and net-marked fish:

$$C = W / FL^3$$

where $W$ = body weight and $FL$ = fork length.

Fish were grouped only as net-marked (damage codes 1-4, Table 1) and unmarked (damage code 0). Differences in mean values for unmarked and net-marked fish were evaluated by unpaired Student's $t$-tests with $P < 0.05$ taken as the maximum level for statistical significance.

## Results and discussion

The only significant differences between net-marked and unmarked fish were in measures of absolute size (mean fork length, body weight, and maximum girth), which were greater for unmarked albacore (Table 2). These data suggest that smaller fish escape drift nets, survive, and are recaptured by the troll fleet more frequently than large fish. This appears to be confirmed by size-frequency distributions for the 217 net-marked and 114 unmarked fish included in this study (Fig. 3A). The two peaks in Figure 3A (at approximately 65 and 80 cm) represent 3- and 4-year-old fish, respectively[2] and imply that 4-year-old individuals predominate the unmarked group. In the net-marked group, 3- and 4-year-old fish are approximately equally represented. This result is, however, more likely due to either a sampling bias of the observers when choosing fish for inclusion in this study, or to time-area variations in fish size composition and the percentage of net-marked fish. The size-frequency distributions of

**Table 2**

Parameters measured to evaluate the effects of escapement from drift nets on the natural mortality of albacore *Thunnus alalunga*. *N* equals the number of observations.

| | Unmarked fish | | Net-marked fish | |

*$P \le 0.05$.

a much larger number of albacore (12,085 unmarked and 381 net-marked individuals[4]; and from which the fish used in this study are a subsample, show that the frequency distributions of 3- and 4-year-old net-marked and unmarked fish are more nearly identical (Fig. 3B); 3-year-old fish were found to be only slightly dominant in both groups.

Our objective in calculating condition factor, relative girth, and relative condition factor (also referred to as relative weight) was to determine if there was any indication of differences in fitness between unmarked and net-marked fish. No differences were found (Table 2). The use and misuse of condition factor and relative condition factor have received much recent attention (Bolger and Connolly, 1989; Cone, 1989; Murphy et al., 1991). The use of such indices in groups of fishes with different mean lengths and size-frequency distributions may not be justified because disparities may be due to differences in body size, rather than to physiological fitness (Cone, 1989, 1990). Because indices of fitness were not different for unmarked and net-marked fish, we considered the question of suitability moot.

No differences were found either in measures of short-term (RNA:DNA ratio) or long-term (relative otolith weight) growth rates (Table 2). The RNA:DNA ratio can be affected by the age of the fish (Haines, 1973); however, it was not corrected for body size (i.e., age) because we found no correlation between it and body weight.

The relative leukocyte counts also did not differ between unmarked and net-marked albacore (Table 2). We assumed that net-marked albacore could show either elevated or reduced leukocyte counts. Acute bacterial infection has been shown to increase leukocyte counts in fish (Wedemeyer et al., 1990). Conversely, reduced leukocyte counts can be caused by elevated circulating corticosteroid levels (an acute stress response) or by chronic bacterial infection causing leukocytolysis (Shreck, 1981; Wedemeyer et al., 1983). The lack of difference between unmarked and net-marked albacore suggests that none of the processes that can affect relative leukocyte counts was occurring in the latter.

We were hampered in interpreting our results because we could not determine precisely how long the fish were at liberty following escapement from drift nets. Based on observations of skipjack and yellowfin tuna held in shoreside tanks at the Kewalo Research Facility (described in Brill, 1992), skin damage resulting from capture generally heals completely within weeks in feeding fish (R. W. Brill, unpubl. observations). Fish with damage codes 1–3 (Table 1), therefore, probably encountered drift nets within one month of recapture. It was impossible to estimate how long fish with damage code 4 had been at liberty or how long net damage remains visible, although Bartoo et al.[2] speculated that fish with damage code 4 may have been at liberty more than a year since encountering a

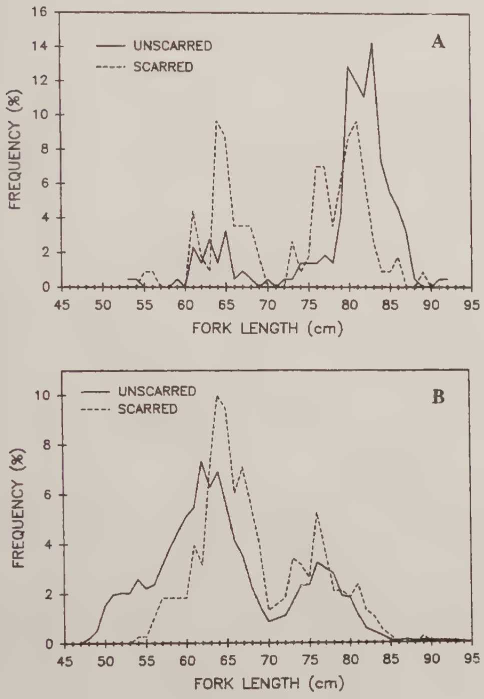

**Figure 3**

Size-frequency distribution of the unmarked and net-marked albacore sampled for our study (**A**) (215 unmarked and 114 net-marked fish) and much larger data set (**B**) (12085 unmarked and 318 net-marked fish) from which the fish used in our study are a subset (N. Bartoo, D. Holts, C. Brown, and L. Halko, SWFSC, La Jolla Laboratory, unpubl. data).

drift net. It is unknown if this is sufficient time for differences in relative otolith weight to become measurable. Boggs and Kitchell (1991) showed that significant weight loss occurs in tunas within one week of starvation. Therefore, it was likely that net-marked fish were at liberty long enough for measures of physiological fitness to become apparent, assuming net-marked albacore had not been feeding prior to recapture. The rate at which relative leukocyte abundance changes in albacore following stress or infection is not known, but in coho salmon (*Oncorhynchus kisutch*) and rainbow trout (*O. mykiss*) leukocyte abundance changes within 96 hours of imposition of stressful conditions (McLeay and Gordon, 1977). Leukocyte abundance should be a good measure of differences in the health of net-marked and unmarked albacore, but the large standard deviation (Table 2) may limit its usefulness in this species.

Failure to detect differences (Table 2) between unmarked and net-marked albacore suggests that the fish escaping from drift nets, and living long enough to become vulnerable to recapture by U.S. trollers, do not suffer increased natural mortality. Most of the fish however, recaptured by trollers are found to be only minimally damaged or to have healed scars (Table 1), which may explain the lack of differences between net-marked and unmarked fish. As shown in Figure 2, there is most likely a spectrum of damage caused during encounters with drift nets. We do not know if the distribution of damage severity in the population of albacore vulnerable to the troll fishery is the same as that of all the albacore that escape drift nets alive. Also, the number of albacore falling out dead, or escaping so badly injured that they succumb before becoming vulnerable to recapture by troll vessels, may well be significant but remains to be determined.

Received: 7 May 1993 / Accepted: 22 June 1993

**Abstract.** We measured the vertical and horizontal movements of striped marlin (*Tetrapturus audax*) off the leeward coast of the Island of Hawaii between 20 November and 18 December 1992 while simultaneously gathering data on water temperature and oceanic currents. Fish movements were monitored by ultrasonic depth-sensitive transmitters, depth-temperature profiles by an expendable bathythermograph system, and oceanic current patterns by an acoustic Doppler current profiler. Like Indo-Pacific blue marlin (*Makaira mazara*), striped marlin near Hawaii spend >85% of their time in the mixed layer (i.e., above 90 m depth). The maximum depth for striped marlin appears to be limited by water temperatures 8 C° colder than the mixed layer, rather than by an absolute lower temperature. We also found that the horizontal displacements of some striped marlin can be strongly influenced by currents.

## Introduction

Striped marlin (*Tetrapturus audax*) are widely distributed in the Pacific and Indian Oceans, but are absent from the Atlantic Ocean (Ueyanagi and Wares 1974, Squire and Suzuki 1990). Like other members of the Istiophoridae, striped marlin are large pelagic predators which make extensive movements. They are not, however, considered as highly migratory as bluefin tuna (*Thunnus thynnus*) or albacore (*T. alalunga*), which undertake rapid and regular transoceanic migrations (Squire and Suzuki 1990). Also, like other members of the Istiophoridae, striped marlin are apparently adapted for attaining and rapidly recovering from extraordinary peak levels of activity, rather than for sustaining high cruising speeds (Johnston and Salmonski 1984, Daxboeck and Davie 1986, Wells and Davie 1986, Wells et al. 1986, Davie 1990). Recently, direct measurements of swimming speeds of Indo-Pacific blue marlin (*Makaira mazara*[1]) confirmed that this species spends the majority of its time moving at relatively slow, and presumably aerobically sustainable, speeds (Block et al. 1992a).

Data are available on the short-term vertical and horizontal movements of striped marlin near the California coast. Holts and Bedford (1990) tracked 11 striped marlin and found that these fish spend most of their time in the mixed layer (19 to 20 °C) and only occasionally descend into water where the temperature is <12 °C. Five of the eight marlin followed for 20 to 48 h moved predominately in one direction at an average ground speed of 1.18 knots (0.607 m s$^{-1}$). The other three fish remained in the vicinity where they had been initially captured and released.

Prior to our study, no information was available on the short-term vertical and horizontal movements of striped marlin near the Hawaiian Islands, an environment quite different from the waters off California (McGary 1955, Seckel 1955, Lynn et al. 1982, Holland et al. 1990a, b, Holts and Bedford 1990). Comparison of the vertical movements and depth distributions of striped marlin near California and Hawaii can reveal factors limiting vertical distribution of this species. Data on vertical movements is additionally useful for resource conservation and fisheries' management. For example, knowledge of the depth distributions of billfishes can enable commercial longline fleets to alter their gear (i.e., adjust hook depths) to minimize the catch of particular species.

Our study also provides the first description of the movements of pelagic fish with simultaneously gathered data on the speed and direction of oceanic currents obtained directly using an acoustic Doppler current profiling system. Previous studies using ultrasonic telemetry to determine tuna and billfish activities (e.g. Yuen 1970, Laurs et al. 1977, Carey and Robinson 1981, Holland et al. 1990 a, b, Holts and Bedford 1990) reported rates of movement which were actually speed over ground (i.e., speed was calculated from positional data) rather than true swimming speed (i.e., speed through the water). Also, without data on oceanic currents, no conclusions could be drawn as to the effects of currents on horizontal displacements. Block et al. (1992 a) partially circumvented these problems by employing telemetry transmitters capable of directly measuring the swimming speed of Indo-Pacific blue marlin, but they lacked a quantitative measurement of currents. Carey and Scharold (1990) directly telemetered swimming speeds of blue sharks (*Prionace glauca*) with current speed and direction estimated from the drift of fishing gear and satellite sea-surface temperature images. These investigators found that both the speed and direction of blue shark movements can be strongly influenced by currents.

---

[1] The common and scientific names for the billfishes used herein follow Nakamura (1985), whereby Atlantic and Indo-Pacific blue marlin are recognized as separate species: *Makaira nigricans* and *M. mazara*, respectively.

## Materials and methods

Two research vessels were employed during our study, the 11 m "Kaahele'ale" and the 53 m National Oceanic and Atmospheric Administration (NOAA) ship "Townsend Cromwell". The hydrophone mounting system aboard the "Kaahele'ale" has been described previously (Brill et al. 1984, Holland et al. 1985). The system aboard the "Townsend Cromwell" was a four-hydrophone array (VEMCO, Halifax, Nova Scotia, Canada) mounted beneath a modified fiberglass depressor wing (V-FIN, Environmental Devices Corporation, Marion, Massachusetts, USA). During tracking operations, the depressor wing was towed amidships ≅5 m beneath the surface. Hydrophones were selected individually by a four-position switch mounted near the receiver.

*Tetraptures audax* were captured by standard commercial monofilament longline gear between 20 November and 18 December 1992. Fishing operations were conducted off the western coast of the Island of Hawaii (156°00'–157°00'W; 19°15'–20°15'N) because the high volcanoes provide a lee of up to ≅10 nautical miles (18.5 km), from the strong northeasterly trade winds. About 120 baited hooks, attached to ≅ 3 to 6 nautical miles (6 to 11 km) of longline, were deployed from the "Townsend Cromwell", soaked for 4 to 8 h, and then retrieved. Individual fish were identified to species and body weights estimated independently by two experienced observers (R. W. Brill and D. B. Holts). Striped marlin that appeared healthy were brought alongside the ship and an ultrasonic depth-sensitive transmitter (VEMCO, Halifax, Nova Scotia, Canada, Model VP-3) was attached to the anterior dorsal musculature using a standard tagging pole. The transmitter attachment system employed the stainless arrowhead design used previously by Holland et al. (1990 a). Immediately after attachment of the transmitter, the fish was released by cutting the leader as close as practical to the fish. No attempt was made to retrieve the hook. Individuals were initially followed by the "Kaahele'ale" until the remainder of the longline gear had been retrieved (usually 1 to 2 h). The "Townsend Cromwell" would then join the other vessel and the fish were tracked in tandem.

The transmitters encoded depth information by varying pulse interval. The output from the transmitters was received aboard both vessels by VEMCO VR-60 ultrasonic receivers. The audio output from the receiver aboard the "Kaahele'ale" was recorded by a standard audio-tape deck. Aboard the "Townsend Cromwell", a frequency counter and IBM PC were used to measure and convert every other pulse interval to depth, and to store the data digitally. The audiotapes recorded aboard the "Kaahele'ale" were later digitized by the computer system aboard the "Townsend Cromwell".

Positional information was obtained aboard both vessels using global positioning system (GPS) satellite receivers. Aboard the "Townsend Cromwell", positional information was also obtained using a satellite navigation system (SATNAV) receiver, LORAN-C receiver, and radar fixes from the nearest point of land. The ships' positions were assumed to be the same as that of the fish and were recorded approximately every 15 min. Oceanic current data (absolute directions and speeds) were collected by an RD Instruments (San Diego, California) acoustic Doppler current profiler (ADCP) aboard the "Townsend Cromwell". Depth-temperature profiles were collected by a Sippican Ocean Systems (Marion, Massachusetts) expendable bathythermograph (XBT) recorder aboard the "Townsend Cromwell". XBT probes were launched approximately every 6 h during a track.

Aggregate depth and temperature distributions were calculated based on 10 m and 1C° bins, respectively (Holland et al. 1990 a, b). These data were expressed as a fraction of the total track time for each fish, and the bins were averaged across all fish. Aggregate temperature distributions also were calculated, where by temperatures are expressed relative to the mixed-layer temperature.

## Results

Estimated body weights, calculated fork lengths, and the duration of the tracks of *Tetrapturus audax* are given in Table 1. Fish 4 apparently died after 4 h, although it had appeared healthy upon release. Its rate of descent (≅10 m $\text{min}^{-1}$) was clearly that of a dead or dying fish, and was far slower than that of a shed transmitter (≅ 30 m $\text{min}^{-1}$, Holland et al. 1990 b). All data from Fish 4 have been omitted. No other marlin succumbed nor shed its transmitter whilst being tracked. All fish, except Fish 6, were followed until they were lost in deteriorating sea conditions: the fish were at the surface and the choppy seas and large swells significantly reduced the range over which the transmitter could be heard. Fish 6 had to be abandoned after 51 h because of lack of ship time.

### Vertical movements and temperature

Vertical movements of the marlin and the simultaneously gathered depth-temperature data are shown in Fig. 1. It is apparent from this figure that striped marlin in Hawaiian waters spend the majority of their time either in, or immediately below, the mixed layer. The fish do make brief excursions into water as cold as 18 °C, but no signif-

**Table 1.** *Tetrapturus audax*. Estimated body weight, calculated fork length, and duration and dates of tracks for six striped marlin equipped with ultrasonic transmitters. Fork lengths were calculated from estimated body weights using weight–length regression equation given in Skillman and Yong (1974)

| Fish No. | Estimated wt (kg) | Fork length (cm) | Duration of track (h) | Date of track |
|---|---|---|---|---|
| 1 | 37 | 210 | 14 | 22–23 Nov. |
| 2 | 45 | 220 | 22 | 24–25 Nov. |
| 3 | 37 | 210 | 23 | 3–4 Dec. |
| 4 | 57 | 230 | 4 | 7 Dec. |
| 5 | 50 | 230 | 41 | 9–11 Dec. |
| 6 | 45 | 220 | 51 | 16–18 Dec. |

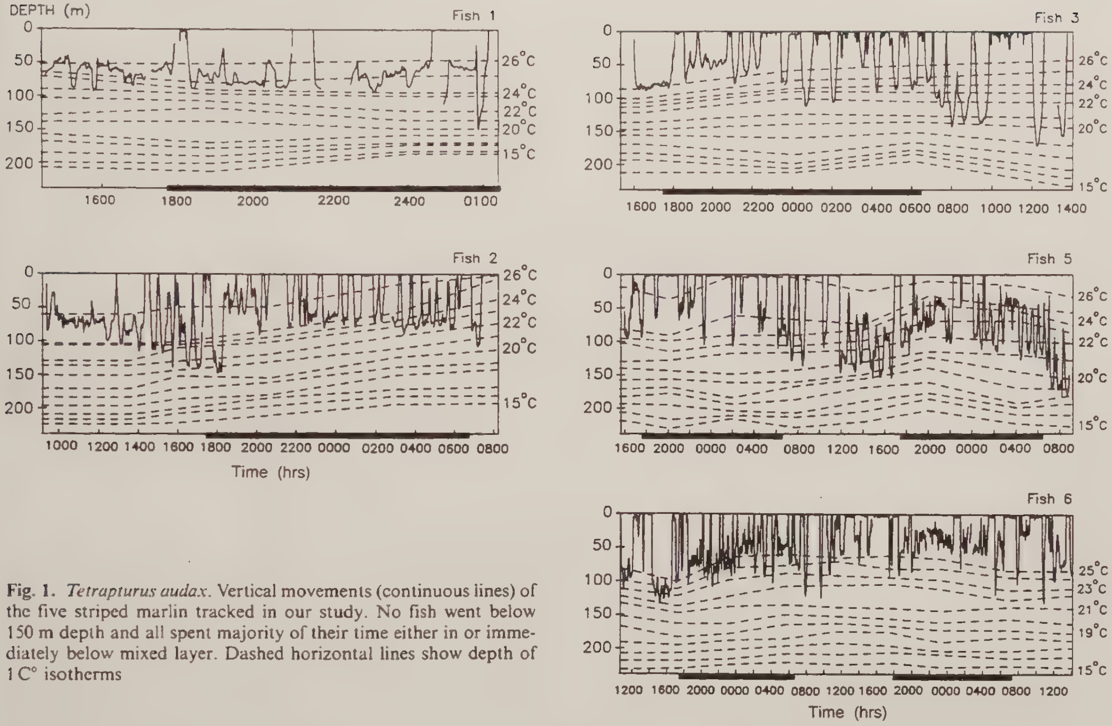

Fig. 1. *Tetrapturus audax*. Vertical movements (continuous lines) of the five striped marlin tracked in our study. No fish went below 150 m depth and all spent majority of their time either in or immediately below mixed layer. Dashed horizontal lines show depth of 1 C° isotherms

icant amount of time is spent at this temperature. Fig. 1 also shows that there are no obvious day–night differences in depth distribution, as seen in tunas (Holland et al. 1990 b).

Fig. 2 summarizes time at depth and time at temperature for all fish. The striped marlin in our study spent almost 30% of their time at depths shallower than 10 m (Fig. 2a). The second peak in the time at depth distribution (51 to 90 m, Fig. 2a) reflects the approximate depth of the bottom of the mixed layer. Fig. 2b shows the time spent at various absolute temperatures and Fig. 2c the time spent at temperatures relative to the mixed-layer temperature. Both (b) and (c) reveal that striped marlin spend >85% of their time either within, or immediately below, the mixed layer.

## Horizontal movements

### *Fish 1*

Fish 1 was captured ≅ 8 nautical miles (15 km) northwest of Keahole Point (Fig. 3) and was released at 11.07 hrs. Because of equipment failure, neither depth nor positional data (except the point of capture) were obtained until 13.00 hrs. The GPS satellite was not transmitting during the majority of the track, so oceanic current information was not obtained. (The ADCP requires real-time data on ship position and speed provided by the GPS receiver). Also, accurate positional information was unobtainable between 18.00 and 22.00 hrs because the GPS satellite was not transmitting and the data from the other navigational systems were unreliable.

Fish 1 moved north, both day and night (Fig. 3), until contact was lost at ≅01.00 hrs in rough water near the edge of the Alenuihaha Channel. The fish had an average ground speed of 2.0 knots (1.0 m s$^{-1}$).

The Alenuihaha Channel is noted for its difficult sea conditions, because the trade winds are funneled between the islands of Hawaii and Maui (the island immediately to the north). Because Fish 1 moved rapidly north into the channel, all subsequent fishing efforts were moved ≅ 20 to 25 nautical miles (37 to 46 km) south.

### *Fish 2*

Fish 2 was released at 09.26 hrs at a point ≅12 nautical miles (22 km) southwest of Keahole Point. It moved south for about 20 min, then turned and headed north for the remainder of the track (Fig. 3). Contact was lost at around 07.30 hrs the following morning in rough sea conditions [≅1 to 2 m swells and 20 to 25 knot (10 to 13 m s$^{-1}$) wind]. The marlin was briefly relocated at 09.05 hrs and then immediately lost again. The fish's course paralleled that of Fish 1 for the entire track. Oceanic current data were not obtained because the GPS satellite was again transmitting only intermittently.

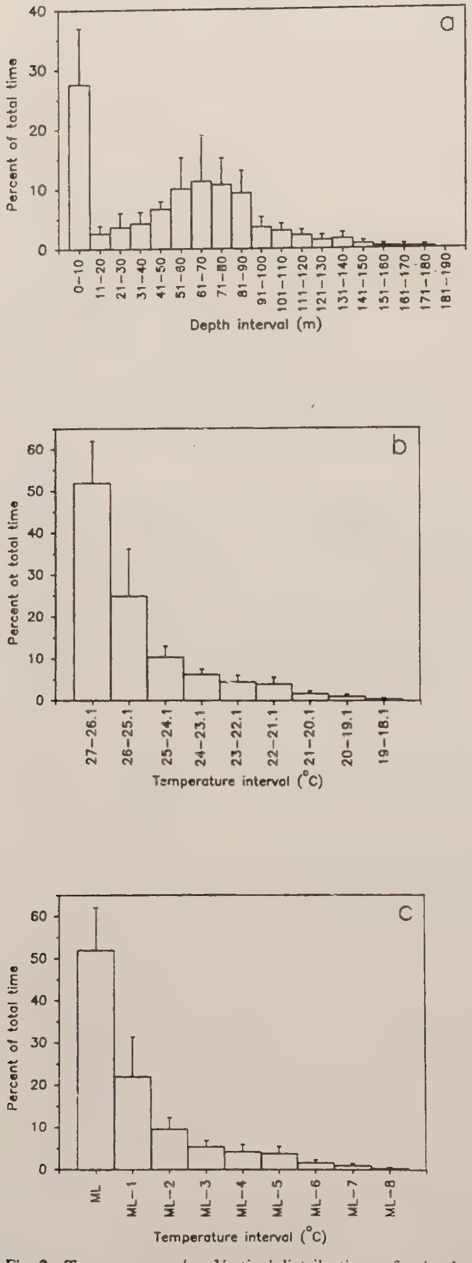

Fig. 2. *Tetrapturus audax*. Vertical distributions of striped marlin in Hawaiian waters expressed as percent time (mean ± standard error of mean) spent at a specific depth (a), at a specific temperature (b), and at temperatures relative to mixed-layer (ML) temperature (c). In (c), ML-1 represents water temperature 1 C° below mixed-layer temperature, ML-2 water temperature 2 C° below mixed-layer temperature, etc. Data confirm that striped marlin spend most of their time in or immediately below mixed layer (i.e., the warmest water available). Maximum depths reached by striped marlin appear to be limited by temperatures that are 8 C° below (ML-8) mixed-layer temperature

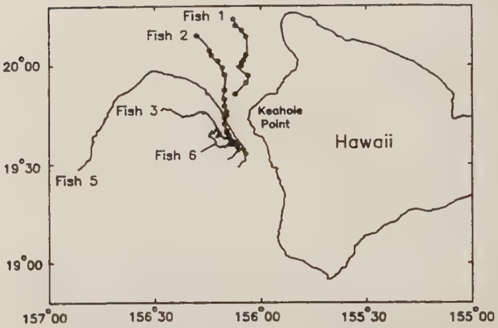

Fig. 3. *Tetrapturus audax*. Island of Hawaii and movements of five striped marlin. Distance scale for fish movements in this and subsequent figures is represented by longitude (1 min of longitude = 1 nautical mile = 1.852 km), with circles indicating hourly positions. Hourly positions have been omitted from tracks of Fish 3, 5, and 6 for legibility

### *Fish 3*

Fish 3 was released at 15.59 hrs in approximately the same area as Fish 2 (Fig. 3). It proceeded north for 2 h, then turned to a more northwesterly heading until first light the following morning (07.00 hrs), when it changed to an almost due westerly course (Fig. 4a). Most (but not all) of the horizontal movements of Fish 3 appear to be due to the prevailing currents (cf. Fig. 4a and b). After $\sim$18.00 hrs (2 h after release), the fish seemed to attempt to maintain a westerly heading but was pushed onto a northwesterly course by the current. The fish's speed over ground at this time was 1.8 knots (0.93 m $s^{-1}$). When the fish reached an area where the currents were more westerly (at ≅07.00 hrs), its speed over ground increased to 3.9 knots (2.0 m $s^{-1}$), presumably because the fish's intended heading and the current were almost parallel.

### *Fish 5*

Fish 5 was released at 16.00 hrs in approximately the same area as Fish 2 and 3 (Fig. 3). This marlin moved northwest for the first night, then gradually turned west and then southwest over the next day. It finally assumed an almost due-south heading during the second night and next morning (Fig. 5a). Average speed over ground for the first 37 h of the track from (16.00 to 07.00 hrs, Fig. 5a) was 2.0 knots (1.0 m $s^{-1}$). The overall displacement of this fish appears to have been caused by currents, since its course parallels the direction of the currents until approximately dawn (07.00 hrs) on the second day (Fig. 5b). The fish may have been attempting to maintain a due westerly course after dawn on the second day, but was pushed to a southwesterly course by the strong (4.2. knots, 2.2 m $s^{-1}$) southerly current.

### *Fish 6*

Fish 6 was released (at 10.42 hrs in roughly the same place as Fish 3 and 5 (Fig. 3). For the first 24 h, the

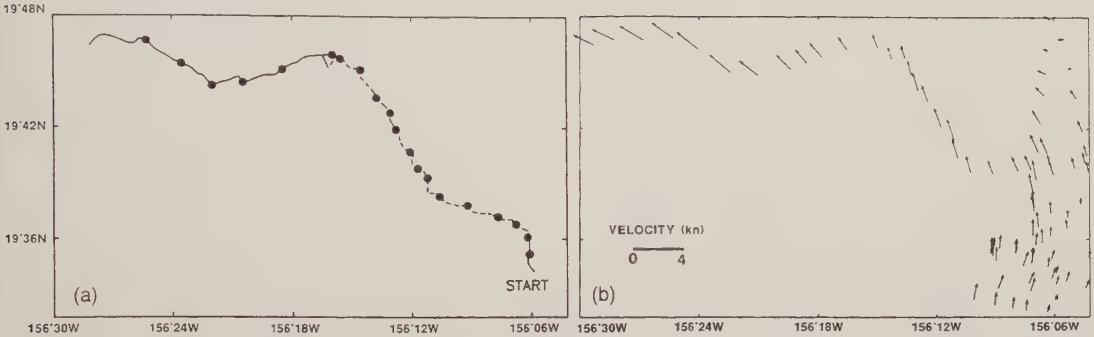

**Fig. 4.** *Tetrapturus audax*. Horizontal movements of Fish 3 (a) and simultaneously gathered oceanic current data (b). Current data are for 20 to 40 m depth, i.e., shallowest depth range from which reliable data can be obtained by acoustic Doppler current profiler. For current speed, 4 knot scale-line = 2.06 m $s^{-1}$. Here and in Figs. 5 and 6, continuous portion of trace indicates daylight movements and dashed portion nighttime movements

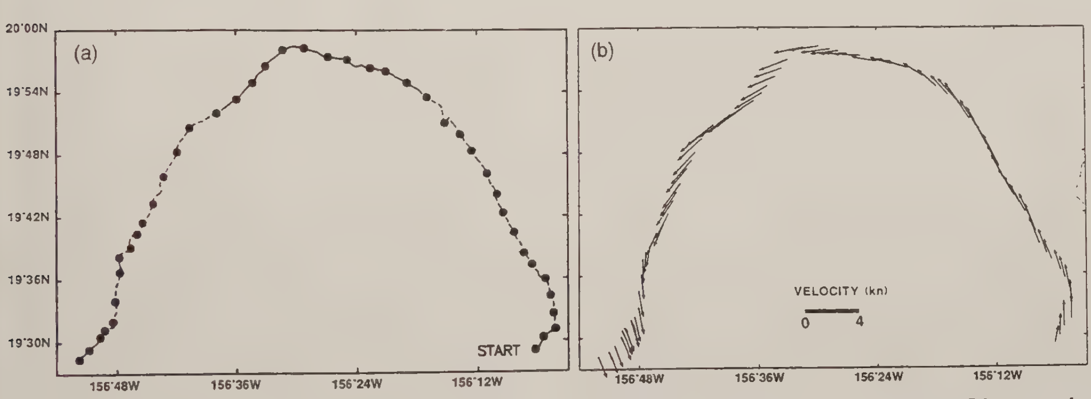

**Fig. 5.** *Tetrapturus audax*. Horizontal movements of Fish 5 (a) and simultaneously gathered current data (b). Fish's movements appeared to be strongly influenced by current direction for most (37 h) of track. During last 5 h (07.00 to 11.00 hrs), fish appeared to attempt to hold a westerly course, but was pushed to southwest by a strong (4.2 knots, 2.2 m $s^{-1}$) southerly current

"Kaahele'ale" followed the marlin while the "Townsend Cromwell" mapped the local current field. The fish moved in a looping pattern (Fig. 6a), so that it remained in the same area rather than moving off as the other marlin had done. Unlike the other fish, the movements of Fish 6 appear to be almost totally uninfluenced by the northerly-directed current (Fig. 6b). Its speed over ground, however, was strongly influenced by the current. When moving nearly parallel with the current (from the start of the track until ≅ 14.30 hrs), ground speed was about 2.1 knots (1.1 m $s^{-1}$). When clearly moving against the current (from ≅14.30 to 18.00 hrs), its ground speed was considerably slower (0.7 knots, 0.36 m $s^{-1}$).

## Discussion

The depth preferences of the *Tetrapturus audax* in our study are similar, but not identical, to those of striped marlin tracked off California by Holts and Bedford (1990). During both studies, the fish spent a significant amount of time in the upper 10 m. Three of the eight fish tracked by Holts and Bedford did not descend below 40 m, and the deepest dive was 93 m. The deepest descent observed during our study was ≅170 m, and our fish spent ≅40% of their time between 51 and 90 m. Our results are consistent with those of Boggs (1992), who found the catch rates of striped marlin near the Hawaiian Islands to be highest for longline hook fishing between 40 and 120 m.

It seems likely that the depth distribution of striped marlin is strongly influenced by water temperature rather than by an absolute depth preference. Comparison of our data with those of Holts and Bedford (1990), reveals that striped marlin do not have an absolute temperature preference. The fish we followed spent ≅80% of their time between 25.1 and 27 °C, and never ventured in water colder than 18 °C. In contrast, because of the lower mixed-layer temperature, the striped marlin tracked off California spent the majority of their time between 20

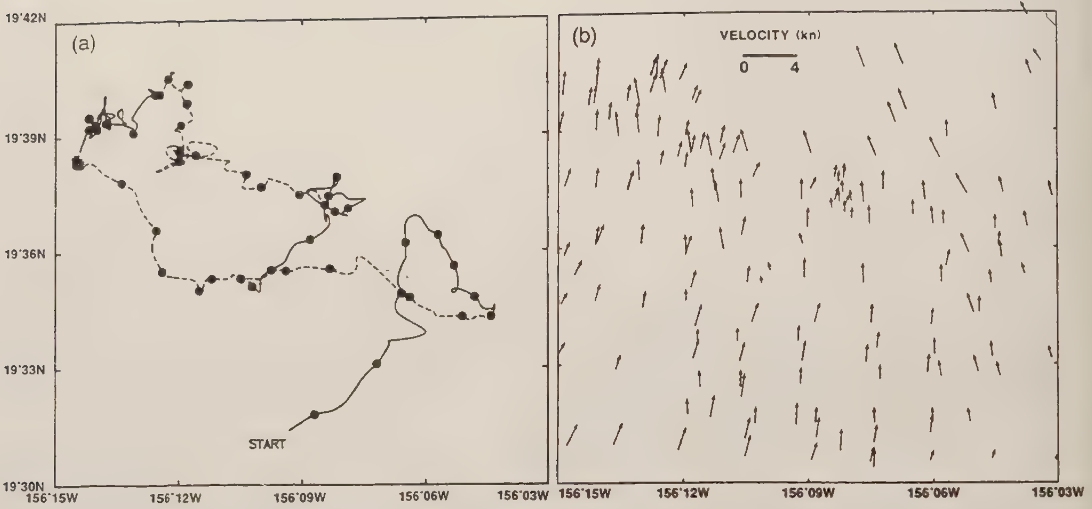

**Fig. 6.** *Tetrapturus audax*. Horizontal movements of Fish 6 (a) and simultaneously gathered current data (b). Unlike other striped marlin tracked during our study, and despite a relatively strong (≈2.5 knots, 1.3 m s$^{-1}$) northerly current, fish remained in relatively small area by moving in looping pattern

and 21 °C, and regularly penetrated into waters of 14 °C, or even 12 °C. When temperature is expressed relative to the mixed layer (Fig. 2c), however, the distributions appears to be the same for both groups. Striped marlin near the Hawaiian Islands and near California both spent the vast majority of their time either in the mixed layer or in water no colder than 2 C° below that of the mixed layer. No fish in either study descended into waters that were more than 8 C° colder than the temperature of the mixed layer. This similarity in behavior occurred in spite of the fact that the fish tracked by Holts and Bedford were somewhat larger (50 to 80 kg) than the fish tracked in our study (37 to 57 kg). In brief, striped marlin appear to spend the majority of their time at the highest water temperature available, and water temperature more than 8 C° below mixed layer temperature forms the floor of the striped marlin habitat. It is the change in water temperature (relative to mixed-layer temperature), rather than absolute temperature, that limits striped marlin vertical movements.

The horizontal displacements of striped marlin off California (Holts and Bedford 1990) and those near the Hawaiian Islands also appear strikingly similar. In both studies, most fish moved in relatively straight lines or slowly curving arcs. Similar horizontal displacements have been observed in Indo-Pacific blue marlin in Hawaiian waters (Yuen et al. 1974, Holland et al. 1990a, Block et al. 1992a). Although oceanic current data were not collected simultaneously in these studies, the paths of Indo-Pacific blue marlin appear to follow the probable cyclonic and anticyclonic eddy patterns (Robinson and Lobel 1985, Lobel and Robinson 1986) which occur on the leeward side of the Island of Hawaii where the fish were tracked.

Relatively straight-line movement is not universal, however. Of the eight striped marlin tracked for 20 h or more by Holts and Bedford (1990), three followed looping courses that kept them in the areas where they were originally caught. Of the five fish tracked in our study, four left the areas where they were caught, and one did not. Because of the overall similarity of the vertical movements in all striped marlin tracked to date, the differences in horizontal movement patterns are probably not due to differences in the extent of injuries acquired during capture. Indeed, Fish 4, the individual that died 4 h after capture, spent the entire time within a few meters of the surface. This appears to be a behavior pattern indicative of badly injured fish. An almost identical situation was observed by Block et al. (1992a). In their study, the one Indo-Pacific blue marlin that was confirmed to have been killed by a shark also spent the entire tracking period (15 h) immediately below the surface, and never ventured deeper than ≅30 m.

The relatively straight-line movement patterns of striped and Indo-Pacific blue marlin contrast sharply with those of skipjack tuna (*Katsuwonus pelamis*), yellowfin tuna, and bigeye tuna tracked near the Hawaiian Islands (Yuen 1970, Holland et al. 1990b). The tunas showed a strong 24 h rhythm in their behaviors. They repeatedly returned to the same areas at the same time for several days, and often returned via different routes. It appears unlikely, therefore, that tuna movements are significantly affected by currents. The reasons for the dramatic differences in the behaviors of tunas and marlins remain unexplained and should be investigated, particularly because tunas are major prey items (in terms of weight) of Indo-Pacific blue and striped marlin (Baker 1966, Brock 1984).

Because our data clearly show that striped marlin movements can be strongly influenced by oceanic currents, we suspect that in studies showing relatively straight-line movements of Indo-Pacific blue and striped marlin (Holland et al. 1990a, Holts and Bedford 1990, Block et al. 1992a, b), some fraction of the overall horizontal displacements of the tracked fish were due to currents. Similar influences of currents on the movements of blue sharks have been observed by Carey and Scharold (1990). Comparisons of "swimming speeds" between studies that do not-telemeter this parameter directly are, therefore, problematic. Note, however, that ground speeds (≅ 1 to 2 knots) of Indo-Pacific blue and striped marlin are remarkably similar whether observed by acoustic telemetry (Holland et al. 1990b, Holts and Bedford 1990, Block et al. 1992b, and present study) or by release and recapture of tagged individuals (Squire 1987). The similarity of these data may reflect either common oceanic current velocities (Lobel and Robinson 1986), common swimming speeds or, most likely, a combination of the two.

Because of the imprecision of estimating geographical position and distances from the tracking vessel to the fish, a zig-zag pattern of fish movement is not really detectable. If fish movement is indeed highly irregular, ground speeds calculated from the tracking vessel's position may underestimate sustainable swimming speeds. In the one study that directly telemetered swimming speeds of Indo-Pacific blue marlin (Block et al. 1992b), the fish swam slower then 2 knots ($1.0 \mathrm{~m~s}^{-1}$) for 93% of the time. Bursts of high speeds, up to 3.6 knots ($1.8 \mathrm{~m~s}^{-1}$), lasted $<1$ min. When not in currents, ground speeds of blue sharks approximated measured swimming speeds, indicating that both Indo-Pacific blue marlin and blue sharks do not dart about (Carey and Scharold 1990, Carey unpublished observations) It seems likely that the same is true for striped marlin.

Communicated by M. G. Hadfield, Honolulu

**Abstract.**–Developmental stages of pygmy poacher, *Odontopyxis trispinosa*, and blacktip poacher, *Xeneretmus latifrons*, are described and illustrated from specimens collected from the northeastern Pacific Ocean. External morphology, pigmentation, and meristic features are described which distinguish larvae of these species from other agonids occurring in these waters.

Postanal pigment patterns, particularly on the caudal finfold, distinguish preflexion larvae. *Odontopyxis trispinosa* larvae possess a semicircular patch of melanophores that covers nearly the entire caudal finfold. The caudal finfold of preflexion *X. latifrons* larvae are void of pigment with the exception of a small patch of melanophores near the ventral margin of the notochord tip. Flexion and postflexion larvae can be distinguished by caudal and anal fin pigmentation, head spination, and adult meristic features.

The family Agonidae is a morphologically diverse group of relatively small, benthic marine fishes. Agonids, commonly called poachers, are characterized by the presence of fused or overlapping bony plates that encase the body. Fifteen genera represented by 25 species occur in the northeastern Pacific (Matarese et al., 1989).

The pygmy poacher *Odontopyxis trispinosa* is a small (to 8.1 cm SL) subtidal agonid distinguished by an elongate body, small vertical spine at the snout tip, and a moderately developed occipital pit divided by a longitudinal ridge. Fin-element counts of *O. trispinosa* are D III-VI, 5-7; A 5-7; P 13-15; V I,2 (Matarese et al., 1989). The blacktip poacher *Xeneretmus latifrons* is a larger (to 19 cm SL) subtidal agonid distinguished by black margins on the dorsal fins and a weakly developed occipital depression (Miller and Lea, 1972; Hart, 1973). Fin-element counts of *X. latifrons* are D VI-VIII, 6-8; A 6-9; P 13-15; V I,2 (Matarese et al., 1989). The presence of spiny scales on the eyeballs distinguishes *X. latifrons* from *X. leiops*. The absence of cheekplates distinguishes *X. latifrons* from *X. triacanthus* (Miller and Lea, 1972; Eschmeyer et al., 1983).

Freeman (1951) hypothesized that these two taxa are closely related phylogenetically and placed them in his subfamily Xeneretminae. The cladistic analysis of Kanayama (1991) demonstrated close relationships between the two taxa which he placed in the subfamily Anoplagoninae.

The geographic range of adult *O. trispinosa* extends from Southeast Alaska to central Baja California. Adult *X. latifrons* occur over a slightly narrower range from Vancouver Island to northern Baja California (Eschmeyer et al., 1983). Both taxa occur at depths of 18–370 m (Miller and Lea, 1972; Hart, 1973). Larval *O. trispinosa* and *X. latifrons* are the most commonly occurring agonids in the California Cooperative Oceanic Fisheries Investigations (CalCOFI) ichthyoplankton collection[1].

---

[1] Moser, H. G., ed. Guide to the early stages of fishes from the California Current region. Southwest Fisheries Science Center, NMFS, P.O. Box 271, La Jolla, CA 92038. In preparation.

Larval development of agonids is poorly known. Washington et al. (1984) and Maeda and Amaoka (1988) reported that formation of most external body parts, including dermal bony plates and spines, begins early in larval development.

Development of the pygmy poacher (*O. trispinosa*) is described for the first time here. Development of *X. latifrons* is clarified based on new material. A partial developmental series (7, 10, 16 mm SL) of *X. latifrons* was previously described by Marliave (1975). Washington et al. (1984) included a single illustration of *X. latifrons* (9.6 mm SL) which differed markedly in appearance from those in Marliave (1975). Matarese et al. (1989) combined the illustrations from both sources to create a complete developmental series. As a result, some confusion exists as to which illustrations in this series are actually those of *X. latifrons* larvae. The following descriptions are the first complete accounts of larval development in the family Agonidae. Characters are presented that permit identification of these larvae from field collections.

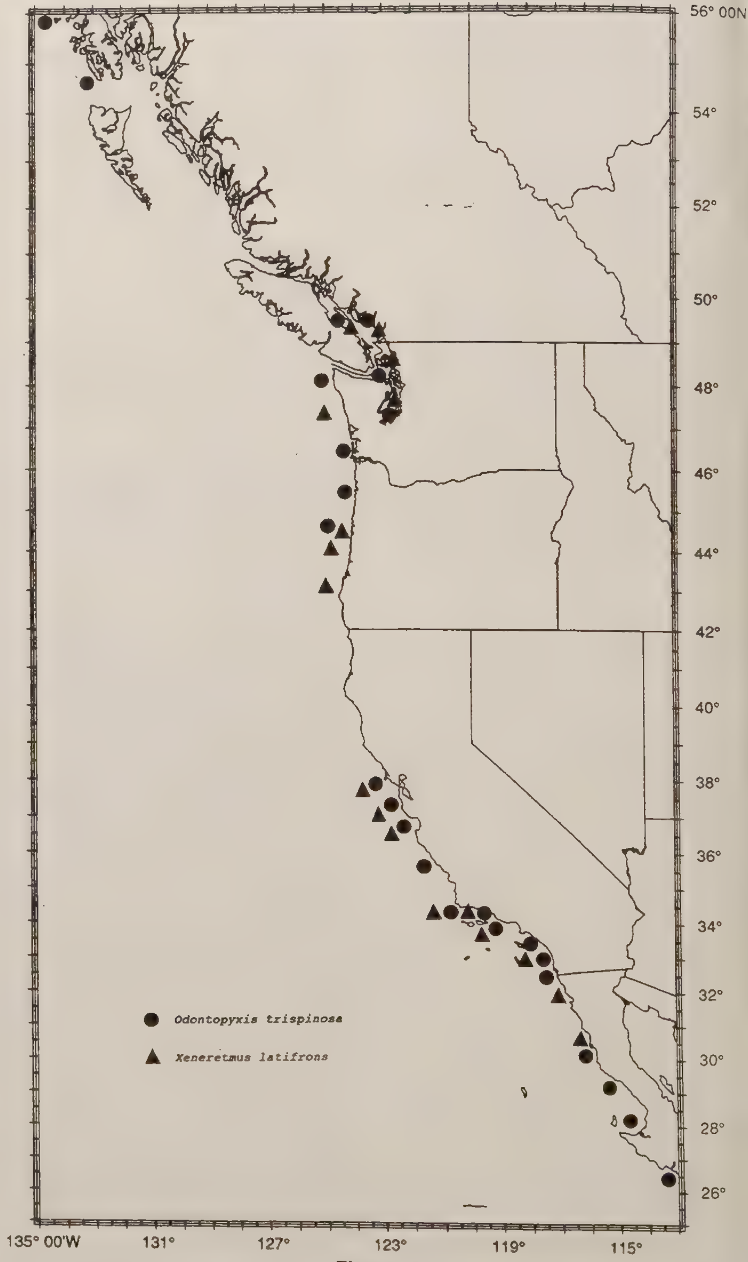

Figure 1

Collection locations of *Odontopyxis trispinosa* and *Xeneretmus latifrons* larvae and early juveniles used in this study.

## Methods

### Specimens

Agonid larvae examined in this study were obtained from collections made off the coasts of Baja California, California, Oregon, Washington (including Puget Sound), Southeast Alaska, and the inside passage waters of British Columbia, Canada (Fig. 1). One hundred and thirty-six *O. trispinosa* (4.3–56.0 mm SL) and 77 *X. latifrons* (4.8–79.0 mm SL) were examined. The largest specimens of each taxa were determined to be adults and are not included in the descriptions. Larvae and juveniles of both taxa were collected with dipnets, 60- and 70-cm bongo nets, Isaacs-Kidd midwater trawls, Tucker trawls, sled trawls, and bottom trawls. Collections were made by the Vancouver Public Aquarium (VPA), Oregon State University (OSU), University of Washington (UW), NOAA's Southwest Fisheries Science Center (SWFSC-CalCOFI program), and the Alaska Fisheries Science Center (AFSC) from the years 1932 to 1991. Specimens are currently housed in the larval fish collections of these institutions. Larvae and juveniles were originally fixed in 3.5 or 5.0% formalin and subsequently transferred and stored in 3.5% buffered formalin or 70% ethanol.

Larvae of *O. trispinosa* and *X. latifrons* were identified using the serial approach. This method uses adult characters to progressively link juveniles to smaller specimens through a continuous sequence of shared similarities. Pigmentation, head spination, body morphology, dermal plates, and meristic features were all used as diagnostic characters. Identification of adult and juvenile specimens was accomplished by using methods of Miller and Lea (1972), Hart (1973), and Kanayama (1991). Nomenclature and taxonomic classification of the family Agonidae follow Kanayama (1991). Developmental series were illustrated by using a camera lucida attached to a dissecting stereomicroscope.

Only melanistic pigmentation is described because formalin fails to preserve color pigments. In the description of pigmentation, the term "band" refers to any aggregation of melanophores that approximates a vertically oriented rectangle. A "bar" also approximates a rectangle but is horizontally oriented. A "patch" is any other distinguishable aggregation of melanophores.

## Measurements

The following measurements were made on 45 larvae and early juveniles of *O. trispinosa* and 45 larvae of *X. latifrons* by using an ocular micrometer in a stereomicroscope:

**Standard length (SL)**—Snout tip to notochord tip prior to development of caudal fin, then to posterior margin of hypural element. (All body lengths in this study are standard lengths.)

**Body depth**—Vertical distance from dorsal to ventral body margin at pectoral-fin base.

**Snout to anus length**—Distance along body midline from snout tip to a vertical line through center of anal opening.

**Head length (HL)**—Snout tip to posterior edge of opercle (to pectoral-fin base in small larvae before opercular margin is visible).

**Head width**—Distance across head between dorsal margins of orbits.

**Snout length**—Snout tip to anterior margin of orbit of left eye.

**Eye diameter**—Greatest diameter of left orbit.

**Pectoral fin length**—Distance from pectoral-fin base to tip of the longest ray.

## Osteology

Selected specimens were cleared and differentially stained to identify cartilage and bone with alcian blue and alizarin red-S (Pothoff, 1984). Skeletal elements and dermal plates were recognized as ossified upon initial uptake of alizarin red-S. Twenty-seven *O. trispinosa* (5.3–41 mm) and 12 *X. latifrons* (7.4–39.2 mm) were cleared and stained for study. Counts of meristic features were made on stained specimens only. Not all stages of development were stained for *X. latifrons* because specimens were limited. Preflexion, flexion, and postflexion stage larvae were stained (Kendall et al., 1984). Nomenclature of skeletal elements follows that used by Leipertz (1985) for *X. triacanthus*. Plate nomenclature follows that of Gruchy (1969) and is described in Figure 2. Terminology of larval head spination follows that proposed for adult

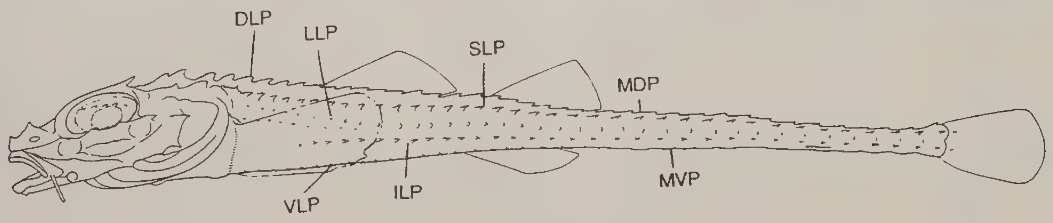

**Figure 2**

Terminology of bony plates in agonid larvae: DLP=dorsolateral; MDP=mid-dorsal; SLP=supralateral; LLP=lateral line; ILP=infralateral; VLP=ventrolateral; MVP=mid-ventral (after Gruchy, 1969).

agonids by Laroche (1986). For larvae with spines and no named analogous adult spine, terminology follows Moser and Ahlstrom (1978) or Richardson and Laroche (1979) for larvae of rockfish *Sebastes* spp. (another Scorpaeniform) (Table 1, Figs. 3 and 4).

## Results

### Development of *Odontopyxis trispinoa*

**Morphology** Larvae of *O. trispinosa* are elongate and slender with mean body depth at the pectoral fin origin of 11.7% SL in preflexion specimens decreasing to 10.7% SL in flexion and postflexion larvae (Tables 2 and 3). Mean head length is 18.4% SL in preflexion larvae and increases to 23.8% SL in juveniles (Table 3). Mean head width is approximately 50.0% HL throughout larval development and decreases to 37.1% HL in juveniles (Table 3). Mean snout length increases from 20.4% HL in preflexion larvae to 27.0% HL in postflexion larvae and eye diameter decreases from 33.3% HL in preflexion larvae to 23.3% HL in juveniles. Mean pectoral-fin length increases from 7.0% SL in preflexion larvae to 19.5% SL in postflexion larvae (Table 3). The gut is moderately long: mean snout to anus distance is 47.9% SL in preflexion larvae and decreases to 33.0% SL in juveniles.

**Pigmentation** Pigmentation in *O. trispinosa* larvae was relatively consistent among specimens and is a useful distinguishing character (Fig. 5).

**Head region** Pigmentation on the head of preflexion larvae is present as rows of melanophores on the upper and lower jaws. A few additional melanophores are present on the snout. Melanophores on the opercular and hyoid regions join the upper and lower jaw pigmentation to form a continuous swath giving larvae a "bearded" appearance (Fig. 5A). In flexion larvae, additional melanophores appear posterior to the eye.

**Lateral body and gut region** The dorsolateral surface of the body above the gut is covered with melanophores with the exception of a patch along the dorsal midline above the pectoral fin. The dorsolateral pigmentation recedes ventrolaterally toward the gut with development and is completely absent in postflexion larvae. Melanophores cover nearly the entire caudal portion of the body in preflexion larvae. In some specimens, the notochord tip is unpigmented. In late flexion and postflexion larvae, pigmentation on the lateral body surface begins to separate gradually into seven bands (Fig. 5D). The first band extends from the posterior region of the first dorsal fin to the ventral body midline immediately posterior to the anus. The second band extends between the first two soft rays of the

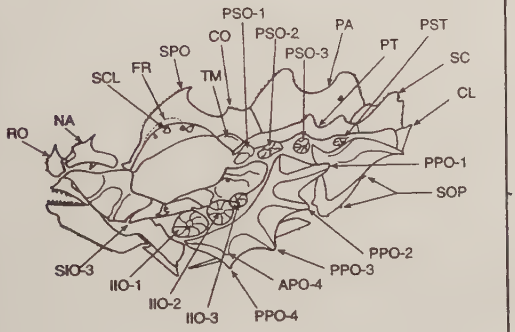

**Figure 3**

Positions and abbreviations of larval head spines and plates in agonids. Based on a 17.2-mm stained larva of *Odontopyxis trispinosa* (modified from Moser and Ahlstrom (1978), Richardson and Laroche (1979), and Laroche (1986)).

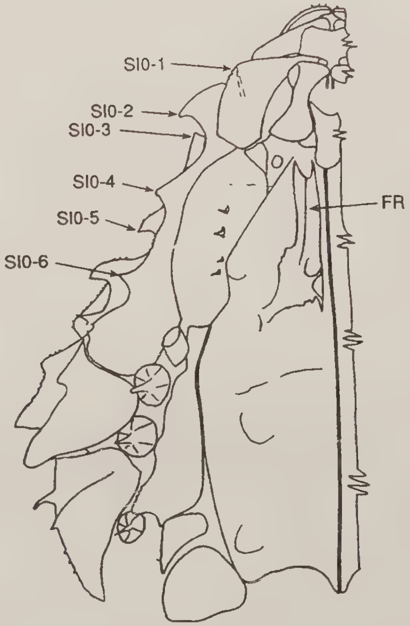

**Figure 4**

Top view above eye showing superior infraorbital and frontal spines of a 17.2-mm SL, cleared and stained *Odontopyxis trispinosa*.

dorsal and anal fins and is connected ventrally to the first band by a bar. The third band extends from the posterior half of the second dorsal fin to the posterior half of the anal fin. The remaining four bands are evenly spaced on the body between the posterior edges of the second dorsal and anal fins and the caudal fin. The third, fifth, and seventh bands are the widest. The posteriormost band of pigmentation in postflexion larvae and early juveniles is located at the hypural margin and is continuous with the caudal-fin pigment.

The entire ventral and lateral surfaces of the gut in preflexion larvae are covered with pigmentation. A dense row of melanophores is present along the ventral midline from the isthmus to the end of the preanal finfold. The ventral midline pigmentation can be distinguished easily in lateral view through the postflexion stage. In some specimens, a small, circular, unpigmented area is present on the lateral surface of the gut posterior to the pectoral-fin rays.

**Fins** The base of the pectoral fin is completely covered with melanophores throughout development. Pigmentation is absent from the pectoral-fin blade, rays, and membrane.

Most preflexion and flexion specimens possess a small group of melanophores on the anterior portion of the dorsal finfold near the body margin over the gut (Fig. 5A). This patch migrates posteriorly with development and becomes the pigmentation seen on the first dorsal fin in postflexion larvae and juveniles (Fig. 5, C and D). A larger patch of melanophores is present at approximately midbody which usually extends to the dorsal edge of the finfold in preflexion larvae. This dorsal midbody patch recedes toward the body and splits into two somewhat triangular-shaped patches of pigmentation in flexion larvae. This larger patch of pigmentation is retained on the second dorsal fin in postflexion larvae and juveniles. The finfold patches roughly correspond to body bands on postflexion and juvenile specimens. Three additional triangular-shaped patches of melanophores are present approximately two-thirds of the distance between the anus and notochord tip on the dorsal finfold and form a continuous region of pigment extending to the caudal finfold. The triangular-shaped patches of pigmentation separate in flexion larvae and disappear as the finfold recedes in postflexion larvae.

### Table 3

Body proportions of *Odontopyxis trispinosa* larvae and early juveniles. Values given for each body proportion are expressed as percentage of standard length (SL) or head length (HL): mean, standard deviation, and range.

| Body proportion | Preflexion | Flexion | Postflexion | Juvenile |
|---|---|---|---|---|
| Sample size | 12 | 8 | 20 | 5 |
| Standard length | 5.7±1.0 (4.3–7.2) | 9.4±1.5 (7.1–11.7) | 14.5±1.9 (11.8–17.7) | 34.6±5.1 (28.0–41.6) |
| Body depth/SL | 11.7±1.0 (10.2–13.4) | 10.7±1.2 (8.4–12.4) | 10.7±0.9 (9.0–12.4) | 10.5±0.7 (9.8–11.6) |
| Snout to anus length/SL | 47.9±1.4 (45.7–50.3) | 46.2±2.5 (43.2–50.8) | 42.5±2.8 (38.9–46.6) | 33.3±1.2 (32.1–34.9) |
| Head length/SL | 18.4±1.2 (16.1–20.5) | 19.4±2.2 (16.5–21.8) | 22.4±1.9 (19.2–25.4) | 23.8±1.5 (22.7–26.4) |
| Head width/HL | 48.7±8.7 (40.4–72.2) | 50.1±9.7 (44.0–73.5) | 47.2±3.3 (43.1–54.9) | 37.1±2.0 (34.4–38.9) |
| Snout length/HL | 20.4±2.3 (16.7–23.8) | 24.8±2.7 (21.7–29.1) | 27.0±2.3 (24.0–32.7) | 24.3±2.1 (21.1–26.3) |
| Eye diameter/HL | 33.3±4.0 (25.7–41.7) | 26.1±1.9 (23.0–29.0) | 23.0±1.5 (19.4–25.3) | 23.3±0.9 (22.2–24.8) |
| Pectoral fin length/SL | 7.0±0.7 (5.3–8.4) | 10.8±2.9 (7.1–14.2) | 19.5±1.7 (16.3–21.3) | 17.1±0.4 (16.6–17.4) |

A small patch of melanophores is present on the anal finfold immediately posterior to the anus. This small patch of pigmentation is a useful character which persists until postflexion when it migrates dorsally with the receding finfold to form the bar between the first and second body bands (Fig. 5D). A large triangular-shaped patch of pigment is present at midbody and extends nearly to the finfold margin in preflexion and early flexion larvae. The large triangular-shaped patch expands ventrally to the finfold margin and becomes more rectangular shaped in late flexion larvae. This is the only pigmentation present on the anal fin in postflexion larvae and juveniles (Fig. 5, C and D). Two additional patches of melanophores are present on the anal finfold in preflexion larvae. These form a nearly continuous region of pigmentation which begins at approximately two-thirds of the distance between the anus and notochord tip which extends to the caudal finfold. This pigmentation breaks apart in late flexion larvae and disappears as the finfold recedes in postflexion larvae.

The posteriormost dorsal and anal finfold pigmentation connect and are continuous with a large semicircular patch of melanophores which covers nearly

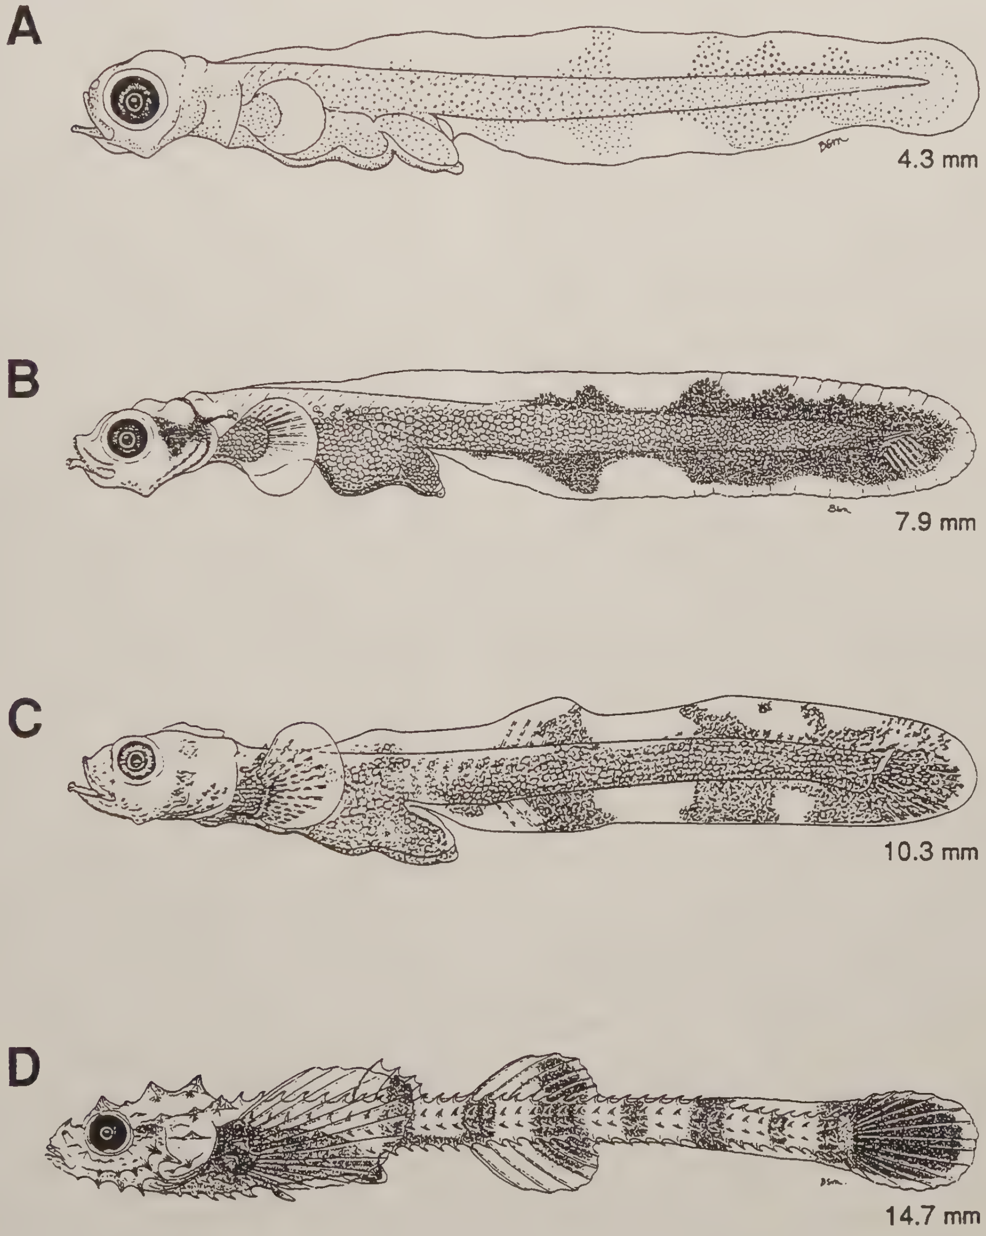

**Figure 5**

Larval stages of *Odontopyxis trispinosa*. (**A**) Preflexion larva 4.3 mm SL, CalCOFI 5405-73.50. (**B**) Early flexion larva 7.9 mm SL, CalCOFI 6304-110.32. (**C**) Flexion larva 10.3 mm SL, VPA, Lambert Channel 4/26/91 No. 7. (**D**) Postflexion larva 14.7 mm SL, CalCOFI 7412-83.44.

the entire caudal finfold. Caudal pigmentation persists throughout development.

**Osteology** Although precursors of some bony structures such as dermal plates and fin rays are discernable as early as 8.0 mm, actual ossification of skeletal elements in *O. trispinosa* does not begin until approximately 12.0 mm.

**Cranium** The parasphenoid and basioccipital bones of the cranium begin to ossify at 11.7 mm. At 13.2 mm, several bones, including the nasal, frontal, parietal, parasphenoid, basioccipital, and exoccipital are completely ossified. The rostral plate, nasal, lateral ethmoid, supraethmoid, vomer, exoccipital, lachrymal, and remainder of the circumorbital series ossify by 14.8 mm. The sphenotic, prootic, epiotic, tabular, and pterosphenoid are ossified by 27.0 mm.

**Spines** Numerous head spines are ossified at 12.6 mm including the nasal, supraocular, the large bilobed parietal, coronal, pterotics, supracleithral, anterior preoperculars and posterior preoperculars 1 and 2. The tympanic, cleithral, opercular, fifth and sixth superior infraorbital spines, and the third and fourth posterior preopercular spines are also ossified at this stage. The frontal spine forms by 13.8 mm but is not visible in lateral view because it is small and located behind the anterior margin of the supraocular spine. The frontal spine becomes overgrown with bone and is difficult to distinguish at 17.2 mm. Interopercular and superior infraorbital spines 1 and 2 begin forming at about 14.2 mm. The rostral and postocular spines and the postocular and posttemporal plates ossify at 14.8 mm. Superior infraorbital spines 3 and 4 and inferior infraorbital plates 1 and 2 are completely ossified at this size. The third inferior infraorbital and sclerotic plates are ossified by 17.2 mm. All spines described here are paired with the exception of the rostral.

**Mandibular region** The dentary, angular, and articular bones of the lower jaw are the first to ossify in postflexion larvae of 11.7 mm. At 12.6 mm, the premaxilla and maxilla are ossified.

**Palatine region** Palatine, quadrate, metapterygoid, mesopterygoid, ectopterygoid, and symplectic bones are ossified at 12.6 mm.

**Opercular region** The preopercle, opercle, interopercle, and subopercle are ossified by 12.6 mm.

**Hyoid region** The basihyal, hypohyal, urohyal, ceratohyal, epihyal, interhyal, glossohyal, and branchiostegal rays are also ossified by 12.6 mm. The hyomandibula is ossified by 27.0 mm.

**Branchial region** The pharyngobranchial teeth are the first structures to ossify by 11.7 mm. Ossification of the pharyngobranchials occurs at about 17.2 mm. The pharyngobranchials begin as four pieces of cartilage that apparently fuse before ossification of the pharyngobranchial teeth. This process, however, was not observed. The epibranchials ($n$=4) and ceratobranchials ($n$=5) also ossify by 17.2 mm. The remaining branchial support structures, including the hypobranchials ($n$=3) and basibranchials ($n$=3), ossify by 27.0 mm.

**Appendicular region** The cleithrum, postcleithrum, and coracoid are ossified by 12.6 mm. The pelvic-fin spine and all pectoral-fin rays, with the exception of the ventralmost, ossify by 12.8 mm. The two pelvic-fin rays and the final (14th) pectoral-fin ray are ossified by 13.2 mm. The supracleithrum ossifies at about 13.8 mm. At 14.8 mm, ossification of the posttemporal is completed. Ossification of the basipterygium occurs at 17.2 mm. The scapula and three radials supporting the pectoral-fin rays are ossified by 27.0 mm.

**Median fins** All dorsal- and anal-fin spines and soft rays are ossified by 12.6 mm (Table 4). Six superior principal rays and five inferior principal rays in the caudal fin are ossified at this size (total=11). One inferior principal (12), and two superior procurrent rays (13, 14) are ossified by 13.2 mm. By 17.2 mm one additional superior (15) procurrent caudal ray is formed which completes the adult count (3+6+6+0=15). Ossification of the epural, hypural plate, and pterygiophores supporting the dorsal- and anal-fin rays is completed by 27.0 mm.

**Vertebral column** Ossification of vertebral elements progresses from anterior to posterior. Notochord flexion begins at approximately 7.0 mm and is completed by 11.8 mm. All, except the posteriormost caudal vertebral centrum, are ossified by 12.6 mm. The urostyle and the anteriormost neural and haemal spines are also complete by 12.6 mm. All abdominal neural spines are complete and three additional haemal spines form anteriorly by 13.2 mm. All vertebral centra are ossified by 13.8 mm and two additional haemal spines have formed. By 14.2 mm, 22 additional haemal spines develop. All neural spines are ossified by 14.8 mm and haemal spines are complete at 15.4 mm.

**Dermal plates** Precursors of the supra (SLP) and infralateral (ILP) plates first appear as small singular spines which are distinguishable at about 8.0 mm. Ossification, however, does not begin until approximately 12.0 mm and progresses from anterior to posterior. Bone develops radially from the base of the spine to eventually form the juvenile/adult dermal plate. By 12.6 mm, ossification of the SLP and ILP series is complete. The dorsolateral and mid-dorsal (DLP+MDP) and the ventrolateral and mid-ventral (VLP+MVP) plate series are complete by 14.8 mm. The lateral line (LLP) plate series begins to form at about 14.0 mm. Lateral line plates are the only plates that begin development as bifurcate spines. Ossification of the LLP series is complete

## Table 4

Meristics of cleared and stained *Odontopyxis trispinosa* larvae and early juveniles. Specimens between dashed lines (——) were undergoing notochord flexion.

*DLP=dorsolateral; MDP=mid-dorsal; SLP=supralateral; LLP=lateral line; ILP=infralateral; VLP=ventrolateral; MVP=mid-ventral.

by 17.2 mm. Breast plates on the ventral surface of the abdomen and pelvic region are complete by 12.6 mm. The number of pectoral-fin base plates in *O. trispinosa* is variable ranging from 3 to 8 among specimens examined. Ossification of pectoral-fin base plates is complete by about 13.8 mm.

## Development of *Xeneretmus latifrons*

**Morphology** Larvae of *X. latifrons* are deeper bodied than *O. trispinosa*; mean body depth at the pectoral-fin origin ranges from 13.3% SL in preflexion specimens to 14.6% SL postflexion (Tables 5 and 6; Fig. 6). Head length increases from 20.3% SL in preflexion larvae to 26.6% SL in postflexion larvae, and snout length as a proportion of head length increases from 18.8% HL in preflexion larvae to 24.4% HL in postflexion larvae (Table 6). Eye diameter decreases from about 37.5% HL in preflexion larvae to 28.4% HL in postflexion larvae, and head width remains approximately 54–55% HL throughout development (Table 6).

Pectoral-fin length increases from 8.4% SL in preflexion larvae to 21.8% SL in postflexion larvae. In preflexion larvae, snout to anus distance is 51.7%

### Table 5

Morphometric measurements (in millimeters) of 45 *Xeneretmus latifrons* larvae. Specimens between dashed lines (— —) were undergoing notochord flexion.

### Table 6

Body proportions of *Xeneretmus latifrons* larvae. Values given for each body proportion are expressed as percentage of standard length (SL) or head length (HL): mean, standard deviation, and range.

| Body proportion | Preflexion | | Flexion | | Postflexion | |
|---|---|---|---|---|---|---|
| Sample size | 15 | | 8 | | 22 | |
| Standard length | 6.3±1.1 | (4.9–8.3) | 9.9±0.6 | (8.9–10.8) | 19.0±9.4 | (10.8–42.0) |
| Body depth/SL | 13.3±1.4 | (11.9–15.7) | 14.2±1.6 | (12.1–15.9) | 14.6±1.6 | (11.0–16.6) |
| Snout to anus length/SL | 51.7±4.5 | (44.7–61.9) | 56.7±2.7 | (53.6–60.8) | 47.4±7.6 | (32.4–57.9) |
| Head length/SL | 20.3±3.0 | (17.1–26.8) | 25.3±2.3 | (21.7–28.7) | 26.6±1.8 | (23.5–30.1) |
| Head width/HL | 53.9±6.0 | (48.2–73.4) | 54.8±2.0 | (50.8–56.7) | 55.6±7.2 | (41.5–67.9) |
| Snout length/HL | 18.8±4.2 | (7.1–26.9) | 22.6±2.0 | (18.7–25.0) | 24.4±2.8 | (19.6–32.3) |
| Eye diameter/HL | 37.5±5.1 | (27.7–45.2) | 29.8±1.2 | (27.9–32.0) | 28.4±2.8 | (25.0–33.7) |
| Pectoral fin length/SL | 8.4±2.8 | (6.1–15.1) | 17.1±4.1 | (9.9–23.6) | 21.8±3.1 | (16.9–26.5) |

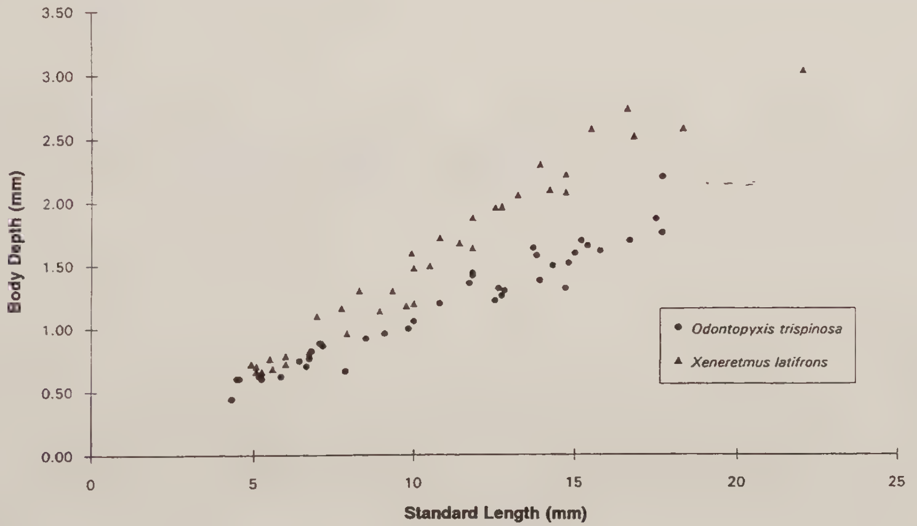

**Figure 6**

Plot of body depth vs. standard length (mm) for larval *Odontopyxis trispinosa* and *Xeneretmus latifrons*.

SL, increases to 56.7% SL during flexion, and decreases to 47.4% SL during postflexion.

**Pigmentation** Pigmentation in *X. latifrons* is consistent among specimens and is a useful distinguishing character (Fig. 7). Because pigmentation on the head and gut regions of *X. latifrons* is so similar to that described previously for *O. trispinosa*, discussion here will be limited to areas of the lateral body and fins that are diagnostically important.

**Lateral body** The lateral surface of the body above the gut in preflexion larvae is covered with melanophores, with the exception of an elongate, unpigmented area along the dorsal midline above the pectoral fin. Melanophores cover nearly the entire caudal region of the body, with the exception of the notochord tip. Melanophores extend along the dorsal and ventral margins of the unpigmented area around the notochord tip (Fig. 7A). By early flexion, melanophores completely cover the notochord tip (Fig. 7B).

Three patches of melanophores appear along the dorsal midline near the notochord tip by about 10.5 mm SL (Fig. 7C). The anterior patch forms the first band which extends from the dorsal margin of the body, posterior to the pectoral-fin base, to the anterior lateral gut area. The second band extends dorsally to connect with pigmentation seen on the first dorsal fin. The third band transverses the body between the posteriormost dorsal spine and the gut. Four or five distinct bands of pigmentation form between the anterior edges of the second dorsal and anal fins and the caudal fin. The first two bands transverse the body between the anterior and posterior margins of the second dorsal and anal fins. One or two bands are present between the posteriormost dorsal- and anal-fin rays and the hypural margin. The last band is the widest and covers the hypural region, extending into the caudal fin approximately 15–20% of its length (Fig. 7, C and D).

**Fins** Melanophores begin to appear on the ventral margin of pectoral-fin base at about 5.0 mm. The pectoral-fin base is completely covered with pigment by 6.0 mm. Pigmentation is always absent from the pectoral-fin blade, rays, and membrane (Fig. 7, A and B).

A small patch of melanophores appears in the dorsal finfold above the constriction of the gut at about 6.0mm (Fig. 7B). This pigmentation later expands and is that seen on the spinous (first) dorsal fin in late flexion and postflexion larvae (Fig. 7, C and D). Posteriorly, an additional patch of pigmentation begins about one-third of the distance between the anus and notochord tip and exhibits an irregular edge, appearing somewhat serrated, below the dorsal margin.

In preflexion larvae, a large patch of melanophores covers most of the anal finfold beginning at approximately one-fourth of the distance between the anus and notochord tip and continuing its entire length. The rela-

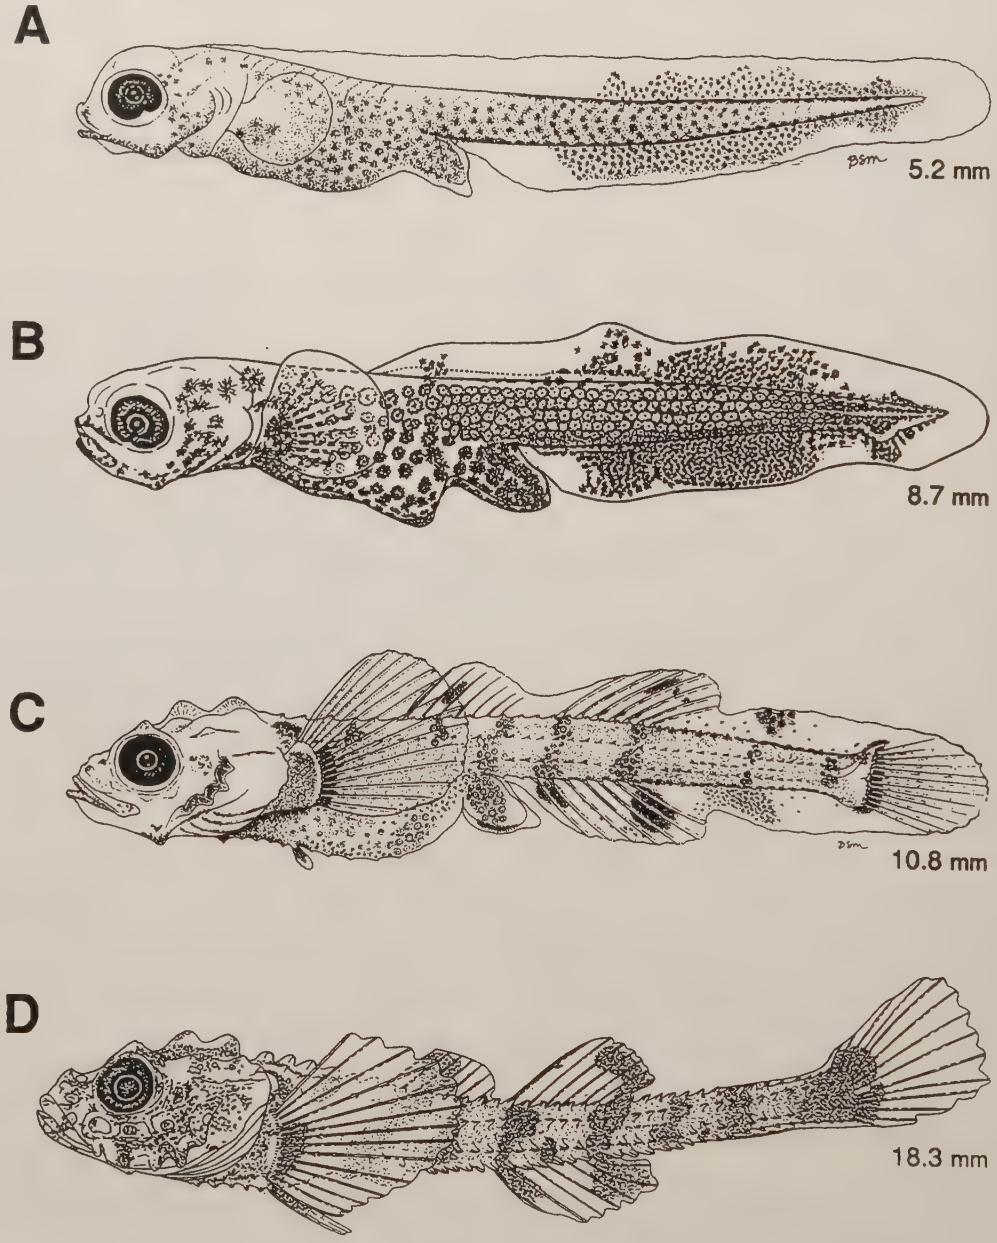

**Figure 7**

Larval stages of *Xeneretmus latifrons*. **(A)** Preflexion larva 5.2 mm SL, CalCOFI 6501BD-83.43. **(B)** Early flexion larva 8.7 mm SL, VPA, Lambert Channel 4/22/90 No. 5. **(C)** Flexion larva 10.8 mm SL, CalCOFI 5403CR-83.48. **(D)** Postflexion larva 18.3 mm SL, VPA, Lambert Channel 5/3/88 No. 4.

tively large unpigmented area anterior of this patch is an important diagnostic feature (Fig. 7, A and B).

Both the dorsal and ventral finfold melanophore patches are constricted nearly to the body margins at a point about 80%–90% of the distance between the anus and notochord tip (Fig. 7B). As notochord flexion progresses, the ventral patch of pigmentation posterior to the constriction on the anal finfold is seen as the post-hypural pigment present on the caudal fin of postflexion specimens (8.7–22.0 mm)(Fig. 7C). This caudal-fin pigmentation extends posteriorly to about 15–20% of the caudal-fin length (Fig. 7, C and D).

The remaining melanophores on the dorsal and anal finfolds migrate toward the body margins as the finfold recedes. Discrete melanophore patches remain on the anterior and posterior margins of the second dorsal and anal fins in postflexion larvae (Fig. 7D).

**Osteology** Although precursors of some bony structures such as dermal plates and fin rays are discernable as early as 8.0 mm, ossification in *X. latifrons* does not begin until approximately 13.0 mm. The sequence of ossification of bony structures in *X. latifrons* is nearly identical to that described previously for *O. trispinosa*. The most important difference to note is that ossification in *X. latifrons* begins later (13.0 mm), progresses more rapidly for lateral body plates, and is slower for most skeletal elements than *O. trispinosa*. The intent here is to highlight important differences between the two taxa.

**Cranium** All parts of the cranium, with the exception of the sphenotic, prootic, epiotic, tabular, and pterosphenoid are ossified at 13.8 mm. These remaining cranial elements ossify at about 30.5 mm.

**Mandibular region** Ossification of all mandibular structures is complete at 13.8 mm.

**Spines** Head spination is generally reduced in *X. latifrons* larvae. *Xeneretmus latifrons* larvae have no inferior infraorbital, postocular, or posttemporal plates and have only four superior infraorbital spines. The rostral spine, which is weaker than that of *O. trispinosa*, and sclerotic plates do not develop until the late postflexion stage (about 25–30 mm). The tympanic and frontal spines are more pronounced in *X. latifrons* larvae than in *O. trispinosa*.

**Palatine region** The palatine, quadrate, metapterygoid, mesopterygoid, ectopterygoid, and symplectic are ossified at 13.8 mm.

**Opercular region** The preopercle, opercle, subopercle, and interopercle are ossified by 13.8 mm.

**Hyoid region** The basihyal, hypohyal, urohyal, ceratohyal, epihyal, interhyal, glossohyal, and branchiostegal rays are ossified by 13.8 mm. The hyomandibula is ossified at 30.5 mm.

**Branchial region** The pharyngobranchial teeth, pharyngobranchials ($n$=4, fused as in *O. trispinosa*), ceratobranchials ($n$=5), and epibranchials ($n$=4) ossify at about 21.0 mm. The remainder of the branchial apparatus including the basibranchials ($n$=3) and hypobranchials ($n$=3), are ossified by 30.5 mm.

**Appendicular region** The cleithrum, postcleithrum, supracleithrum, and coracoid are ossified by 13.8 mm. Pelvic-fin spines and rays and all pectoral-fin rays are complete at 13.8 mm (Table 7). The basipterygium and posttemporal ossify by 21.0 mm. The scapula and three radials supporting the pectoral fin are ossified by 30.5 mm.

**Median fins** All dorsal-, anal-, and caudal-fin spines and soft rays are ossified by 13.8 mm (Table 7). The caudal fin has 6 superior principal, 2 superior procurrent, 6 inferior principal, and 1 inferior procurrent rays (2+6+6+1=15 total). Ossification of the hypural plate and the pterygiophores supporting the dorsal- and anal-fin rays was not complete in the largest specimen examined (39.2 mm).

**Vertebral column** Notochord flexion begins at approximately 8.5 mm and is completed by 11.0 mm. All vertebral centra and the urostyle are ossified by 13.8 mm. All except the two posteriormost neural and three haemal spines are also ossified at 13.8 mm. Ossification of all neural and haemal spines is complete by 14.5 mm (Table 7).

**Dermal plates** All dermal plates are ossified by 13.8 mm. Sequence and direction of formation and ossification is the same as previously described for *O. trispinosa*. *Xeneretmus latifrons*, however, has higher DLP+MDP, ILP, and VLP+MVP lateral body plate series counts than *O. trispinosa* (Tables 4 and 7). A maximum of five pectoral-fin plates was counted in *X. latifrons*.

## Discussion

### Summary comparison of *O. trispinosa* and *X. latifrons* larvae

Larvae of *O. trispinosa* and *X. latifrons* can be distinguished by pigmentation, morphological, and meristic characters.

Larvae of *O. trispinosa* possess a semicircular patch of melanophores that nearly covers the entire caudal finfold. This character is diagnostic and present throughout development. The caudal finfold of preflexion *X. latifrons* lacks pigmentation except for a patch located near the ventral margin of the notochord tip. This patch becomes elongate as notochord flexion progresses and becomes a band at the hypural margin. This band extends onto the caudal fin and may cover as much as 20% of its anterior surface.

Preflexion larvae of *O. trispinosa* possess a small patch of melanophores on the anal finfold immediately posterior to the origin, *X. latifrons* larvae have a large

## Table 7

Meristics of cleared and stained *Xeneretmus latifrons* larvae. Specimens between dashed lines were undergoing notochord flexion.

| 39.2 | 6 | 6 | 7 | 14 | I,2 | 6 | 15 | 26 | 41 | 34 | 15 | 26 | 41 | 38 | 38 | 40 | 38 | 38 |

*DLP=dorsalateral; MDP=mid-dorsal; SLP=supralateral; LLP=lateral line; ILP=infralateral; VLP=ventrolateral; MVP=mid-ventral.

unpigmented region. Flexion and postflexion larvae of *O. trispinosa* possess a single patch of melanophores on the anal fin, *X. latifrons* have two.

Notochord flexion of *O. trispinosa* begins at approximately 7 .0mm and is completed by 11.8 mm. The largest planktonic specimens of *O. trispinosa* collected were 17.7 mm. Settlement probably occurs at approximately this size. Notochord flexion of *X. latifrons* begins at approximately 8.5 mm and is completed by 11.0 mm. The largest planktonic specimens of *X. latifrons* collected were 22.0 mm.

*Xeneretmus latifrons* larvae are deeper bodied than *O. trispinosa*. *Xeneretmus latifrons* also has a wider head than *O. trispinosa* at all stages of development. Single barbels are present at the corners of the mouth at about 15.0 mm in *O. trispinosa* and 18.0 mm in *X. latifrons*. A distinct heart-shaped occipital pit is present in *O. trispinosa* after about 15.0 mm. Postflexion larvae of each taxon are also distinguishable by adult meristic characters.

Ossification of most skeletal elements in *O. trispinosa* begins earlier and is completed at smaller sizes than in *X. latifrons*. Head spination in *X. latifrons* is generally reduced and dermal plates are absent on the head region. The caudal-fin ray complement in *X. latifrons* (2+6+6+1) is notably different than in *O. trispinosa* (3+6+6+0). Ossification of the pterygiophores supporting the dorsal and anal fins, and the hypural plate is complete by 27.0 mm in *O. trispinosa*, but was not evident in cleared-and-stained specimens of *X. latifrons* examined in this study (up to 39.2 mm). This indicates that transformation from larval to juvenile stages in *X. latifrons* occurs at much larger sizes than in *O. trispinosa*. Ossification of dermal body plates occurs in nearly identical sequence, but *X. latifrons* has more plates in the DL+MD, IL, and VL+MV series. Dermal plate formation in *X. latifrons* is complete at a slightly smaller size than in *O. trispinosa*.

The preceding descriptions eliminate the confusion in the literature concerning these larvae which resulted from previous misidentifications (page 463 of Matarese et al. (1989) and Figures A, B, and D from Marliave (1975) are larvae of *O. trispinosa* misidentified as *X. latifrons*; Figure C from Washington et al. (1984) is *X. latifrons*).

## Comparison of *O. trispinosa* and *X. latifrons* larvae with other known larval agonids

Presently, larvae of 12 of 25 agonid taxa occurring in the northeastern Pacific Ocean can be identified based on single illustrations or complete developmental descriptions. Of these 12 taxa, only *O. trispinosa* and *X. latifrons* described here are complete, illustrated at all stages of development and include discussions of ossification sequence.

By using body morphology, pigmentation, and meristic characters, larvae of *O. trispinosa* and *X. latifrons* are distinguishable from other northeastern Pacific

**Table 8**

Summary of characters useful in identifying larval and juvenile agonids from the northeastern Pacific Ocean.*

| | Characters | | | | | |
|---|---|---|---|---|---|---|
| Species | Body depth | Pectoral fin length | Pigmentation | Number of dorsal fins | Pectoral fin rays | Vertebrae |
| *Aspidophoroides monopterygius* | Slender | Elongate | Light | 1 | 9–10 | 51–53 |
| *Bothragonus swanii* | Deep | Normal | Moderate | 2 | 10–12 | 29–31 |
| *Chesnonia verrucosa* | Moderate | Elongate | Light | 2 | 14–15 | 34–38 |
| *Hypsagonus mozinoi* | Deep | Normal | Heavy | 2 | 11–12 | 34 |
| *H. quadricornis* | Deep | Normal | Heavy | 2 | 12–14 | 36 |
| *Leptagonus leptorhynchus* | Moderate | Normal | Heavy | 2 | 13–15 | 42–44 |
| *Ocella dodecaedron* | Moderate | Normal | Light | 2 | 14–16 | 38–39 |
| *Odontopyxis trispinosa* | Moderate | Normal | Moderate | 2 | 13–15 | 37–42 |
| *Percis japonicus* | Deep | Normal | Heavy | 2 | ¯12 | 40,42 |
| *Stellerina xyosterna* | Moderate | Elongate | Light | 2 | 17–19 | 34–37 |
| *Ulcina olriki* | Slender | Elongate | Moderate | 1 | 13–16 | 38–40 |
| *Xeneretmus latifrons* | Moderate | Normal | Moderate | 2 | 13–15 | 39–43 |

*Sources: Illustrations of *A. monopterygius, C. verrucosa, H. quadricornis* and *S. xyosterna* are from Washington et al. (1984); *B. swanii* is from Marliave (1975); *H. mozinoi* is from Matarese et al. (1989); *L. leptorhynchus, O. dodecaedron*, and *P. japonicus* are from Maeda and Amaoka (1988); *U. olriki* is from Dunbar (1947). Pectoral-fin ray and vertebral counts are from Matarese et al. (1989), with the exception of *H. mozinoi* and the lower count for *P. japonicus* which are from Kanayama (1991).

agonid larvae for which published illustrations are available. (Table 8). Larvae of *Hypsagonus mozinoi*, *H. quadricornis*, and *Percis japonicus* are deeper bodied, have notably shorter snout to first dorsal fin distances, are more heavily pigmented, and have lower vertebral and dermal plate counts than *O. trispinosa* and *X. latifrons* (Washington et al., 1984; Maeda and Amaoka, 1988; Matarese et al., 1989). *Bothragonus swanii* larvae have a very similar body morphology to *H. mozinoi*, *H. quadricornis*, and *P. japonicus* but have considerably less pigmentation (Marliave, 1975).

Larvae of *Chesnonia verrucosa* and *Stellerina xyosterna* have similar body morphologies to *O. trispinosa* and *X. latifrons* but have notably larger pectoral fins with bands of pigmentation on or near their posterior edges (Washington et al., 1984; Matarese et al., 1989). *Ocella dodecaedron* and *Leptagonus leptorhynchus* larvae have a similar body morphology to *X. latifrons*. However, pigmentation of *O. dodecaedron* is more sparse and that of *L. leptorhynchus* is heavier (Maeda and Amaoka, 1988).

Larvae of *Ulcina olriki* are distinguished from *O. trispinosa* and *X. latifrons* by having larger pectoral fins with pigmented edges and only a single dorsal fin (Dunbar, 1947). Larvae of *Aspidophoroides monopterygius* (= *A. bartoni*) have extremely slender bodies, a long pectoral fin with a low fin-ray count, higher vertebral and body plate counts, and a single dorsal fin (Maeda and Amaoka, 1988; Matarese et al., 1989). Studies such as this and others planned for the future are the first steps for providing diagnostic information necessary to accurately identify early life history stages of this interesting family of fishes.

## Acknowledgments

The authors would like to thank Arthur Kendall Jr., Ann Matarese (AFSC-Seattle), and Wayne Laroche (Stonefish Environmental and Taxonomic Services) for critical review of the manuscript. Much needed specimens were provided by Wayne Laroche, Jeffrey Marliave (VPA), H. Geoffrey Moser (SWFSC), Theodore Pietsch (UW), Richard Rosenblatt (SIO), and Bruce Wing (AFSC-Auke Bay). Douglas Markle (OSU) provided specimens and station data from collections off the Oregon coast. Barbara Sumida-McCall illustrated the specimens shown in Figure 5, A, B, and D, and in Figure 7, A and C (from Moser, ed.[1]). Beverly Vinter illustrated specimens shown in Figure 5C and in Figure 7, B and D. Illustrations by Barbara Sumida-McCall were partially funded by the U.S. Minerals Management Service through an interagency agreement (Number 10396).

# THE EFFECT OF NATURAL VARIABILITY OF LIFE-HISTORY PARAMETERS ON ANCHOVY AND SARDINE POPULATION GROWTH

JOHN L. BUTLER, PAUL E. SMITH, AND N. CHYAN-HUEI LO
Southwest Fisheries Science Center
National Marine Fisheries Service, NOAA
P.O. Box 271
La Jolla, California 92038

## ABSTRACT

The northern anchovy (*Engraulis mordax*) and Pacific sardine (*Sardinops sagax*) populations were modeled with a stage-based matrix to examine how natural variation of life-history parameters affects per capita growth. In the model northern anchovy (*Engraulis mordax*) population, the greatest change in growth results from natural variation in the duration of, and the instantaneous mortality rate of, the early and late larval stages. In the model Pacific sardine (*Sardinops sagax*) population, the greatest change in growth results from natural variation in the duration of, and the instantaneous mortality rate of, the late larval stage. Temperature determines the duration of both egg and yolk-sac larval stages and the rate at which prerecruit sardine and anchovy mature. We believe that changes in the duration of both egg stages and yolk-sac larval stages may have greater effects on population growth than changes in any single stage.

## RESUMEN

Se modelaron las poblaciones de anchoveta nortẽna (*Engraulis mordax*) y de sardina Monterrey (*Sardinops sagax*). Usando matrices basadas en estadios de vida, se examinó como la variación natural de los parámetros de las fases vitales afecta el crecimiento per capita. En las poblaciones modelo de anchoveta, el mayor cambio en crecimiento fué resultado de la variación natural de la duración y de la tasa instantánea de mortalidad de los estadios tempranos y tardíos de las larvas. En la población modelo de sardina, el cambio mayor en crecimiento fué resultado de la variación natural de la duración y tasa instantánea de mortalidad de los estadios larvales tardíos. La temperatura determina la duración de los estadios huevo y saco vitelino, así como la tasa a la cual las sardinas y anchovetas pre-reclutas maduran. Creemos que cambios en la duración de estadios huevo y de saco-vitelino podrían tener efectos mayores en el crecimiento poblacional que cambios en cualquiera de los estadios individuales.

## INTRODUCTION

The Pacific sardine population (*Sardinops sagax*) in the northeast Pacific Ocean has greatly fluctuated during this century. Biomass peaked in 1932 at about 3,600,000 MT (Murphy 1966) and then fell to about 6,000 MT in 1975 (Barnes et al. 1992); it remained low for the rest of the decade. Recently the sardine has begun to recover off California and northern Baja California. Since the early 1980s the population has grown steadily at about 50%$\cdot$y$^{-1}$ (Smith et al. 1992) to reach a biomass of about 340,000 MT in 1991 (Barnes et al. 1992).

The northern anchovy (*Engraulis mordax*) population off California and Mexico has also undergone large changes. Stock size was low in the 1950s and 1960s, grew rapidly in the early 1970s, and reached a maximum biomass of about 1,700,000 MT in 1974 (Lo and Methot 1989). In the early 1970s, the northern anchovy's population growth rate was also about 50%$\cdot$y$^{-1}$.

Scale-deposition rates in anaerobic sediments indicate that both populations have undergone similar wide fluctuations before and since the development of modern fisheries (Soutar and Isaacs 1974; Smith and Moser 1988). Sardines appear to fluctuate more rapidly than anchovy, although Lasker and MacCall (1983) pointed out that calibrating scale-deposition rate to population size may exaggerate changes in total abundance of the species. Nevertheless the scale data indicate that large population fluctuations are common among these clupeoid stocks in the absence of fisheries, and that these fluctuations must be due to changes in the physical and biotic environment.

Global climate change will significantly affect the physical environment of marine ecosystems. Potential effects include changes in sea-surface temperature and in the intensity of upwelling (Bakun 1990). These physical changes will affect the distribution and dynamics of fish stocks. The stage-based matrix described here provides a means to test hypotheses concerning how environmental change will affect fish populations.

A number of important life-history parameters of marine fish are directly affected by changes in temperature. Temperature and food densities affect

[Manuscript received January 27, 1993.]

growth at all stages. Instantaneous mortality of eggs and larvae are also a function of temperature (Houde 1989), and the size and age of first reproduction varies with temperature (Methot 1986). Because all of these parameters are linked by temperature, it is possible that some of the effects of global climate change can be investigated by means of stage-based population models and existing knowledge.

Previous attempts to model anchovy or sardine populations using stage-based models have been hampered by (1) a lack of theoretical framework (Smith 1985) or (2) an incomplete understanding of the range of variation for important life-history parameters (Smith 1985; Smith et al. 1992). Our objective in this paper is to model anchovy and sardine populations by using a stage-based matrix (Lefkovitch 1965) as a theoretical framework and to examine how natural variation of stage-specific vital rates affects population growth rates.

Vital rates for each stage of the model were obtained from the literature. For some stages the vital rate is unknown; in such cases we obtained a vital rate from literature on other populations of sardines and anchovy, or estimated by the methods described below. We have thus compiled the most comprehensive estimates of life-history parameters to date. We also examined the effect of fishing mortality on the two populations.

## METHODS

The matrix (**A**) describes the transition of a population from time $t$ to time $t+1$ in terms of vital rates of each life stage:

$$\mathbf{A}n_t = n_{t+1} \qquad (1)$$

where $n_t$ is a vector describing the population at each stage at time $t$, and **A** is the transition matrix:

$$\mathbf{A} = \begin{array}{cccccc} P_1 & m_2 & . & . & . & m_q \\ G_1 & P_2 & 0 & . & 0 & 0 \\ 0 & G_2 & P_3 & 0 & . & 0 \\ . & . & . & . & . & . \\ 0 & 0 & 0 & . & G_{q-1} & P_q \end{array} \qquad (2)$$

where $P_i$ is the probability of surviving and staying in stage $i$, $G_i$ is the probability of surviving and growing into the next stage, and $m_i$ is the maternity per fish per unit time (d); $i = 1, . . q$.

Both $P_i$ and $G_i$ are functions of the survival probability ($p_i$) and the growth probability ($\gamma_i$) (Caswell 1989):

$$p_i = e^{-z_i} \qquad (3)$$

and $$P_i = p_i(1 - \gamma_i) \qquad (4)$$

and $$G_i = p_i\gamma_i \qquad (5)$$

where $$\gamma_i = [(1 - p_i)p_i^{d_i-1}]/[1 - p_i^{d_i}] \qquad (6)$$

where $z_i$ is the daily instantaneous mortality rate (IMR) and $d_i$ is the duration ($d$) within the ith stage. The derivation of $P_i$, $G_i$, and $\gamma_i$ follow Crouse et al. (1987) and Caswell (1989).

The maternity parameter $m_i$ is computed as:

$$m_i = (\sum_j[f_j w_{ij}])/\sum_j[w_{ij}] \qquad (7)$$

where $f_j$ (the age-specific fecundity rate) is the number of eggs per fish of age $j$ per unit time, and $w_{ij}$ is the proportion of fish that are of age $j$:

$$w_{ij} = \exp(-z_i t_{1j}) - \exp(-z_i t_{2j}) \qquad (8)$$

where $t_{1j}$ is the beginning and $t_{2j}$ is the ending age for the fish of age group $j$. Briefly, total annual production of eggs was estimated for each size class and apportioned on an average daily basis.

Anchovy spawn each day from sunset to midnight, with the peak at 2200 (Lo 1983). Sardine spawn between 2000 and 0400, with the peak near midnight (Smith 1973). In the model, the fecundity estimates of sardine were assumed to be knife-edged at 0000 h, and the fecundity estimates of anchovy were corrected for mortality from spawning (2200) to census at the end of day one (2400) by: $F_i = Q_i m_i$, where $Q_i$ is the probability of surviving from spawning to the first census and $Q_i = e^{-zt}$, where $z$ is the daily instantaneous mortality rate and $t$ is the time from peak spawning to the time of census.

The dominant eigenvalue $\lambda$ of the matrix represents the population growth rate. If $\lambda = 1.0$, the population is stationary, and if $\lambda = 1.5$, the population is growing at 50%·d$^{-1}$. The results are given in annual growth of the population, which is equal to $\lambda^{365}$, since the duration of stages was measured in days. We estimated $\lambda$ from the dominant eigenvalue of the matrix **A** using MathCAD.

We measured the importance of natural variability in mortality, duration, and fecundity parameters at each stage by calculating $\lambda$ for a series of values for each parameter. Initial conditions were a stationary population, and we examined changes of $\lambda$ with known deviations of each stage-specific vital rate.

### *Anchovy Vital Rates*

The northern anchovy is a multiple spawner (Hunter and Goldberg 1980). Annual fecundity is the number of eggs released per spawning (batch fecundity) times the number of spawnings in a season. The variation in batch fecundity and the variation of spawning rate with age are well known (Hunter and Goldberg 1980; Hunter and Macewicz 1980; Parrish et al. 1986; Alheit, in press), but little is known of the interannual variation in number of spawnings per year. The spawning rate for northern anchovy varies interannually from once every 6.25 days to once every 10.6 days (Bindman 1985). At that rate the average female would spawn 5 to 10 times during the March–April spawning season. Some spawning occurs all year long, and Parrish et al. (1986) found evidence that the number of spawnings per year increases with age. The fecundity used in the model was a daily rate that apportioned spawning equally over the year (table 1). In reality, spawning is seasonal, but modeling the seasonality of spawning is beyond the scope of this paper. The daily fecundity was divided by two to estimate the number of female eggs.

The anchovy population was modeled on the basis of nine stages, as defined by Smith (1985). We derived minimum, maximum, and best estimates of daily instantaneous mortality rates and duration of each stage from literature values (table 2). The durations of the egg and yolk-sac stages are derived from incubation experiments at different temperatures (Lo 1983). Mean duration was based on the development rate at 16°C, which is about the average temperature for anchovy eggs. Mortality rates of egg, yolk-sac, and larval stages were estimated from field studies (Stauffer and Picquelle 1981; Bindman 1985). Durations of the larval and juvenile stages are from field studies of growth rates derived from daily increments in the otoliths (Methot and Kramer 1979; Butler 1987, 1989).

TABLE 1

Fecundity Schedule of Northern Anchovy

| Year | Wt (g) | Spawns per year | Batch (eggs) | $M(x)$ | $L(x)$ $z = .76$ | $LxMx$ | Daily |
|---|---|---|---|---|---|---|---|
| 0 | 0.0 | 0.0 | | | | | |
| 1 | 8.7 | 5.3 | 4237.8 | 22460.3 | 1000 | 11230170 | 30747 |
| 2 | 14.6 | 11.9 | 7860.4 | 93538.8 | 468 | 21888070 | 59926 |
| 3 | 18.3 | 19.2 | 10132.2 | 194538.2 | 216 | 21010130 | 57523 |
| 4 | 21.2 | 23.5 | 11912.8 | 279950.8 | 102 | 14277491 | 39090 |
| 5 | 24.5 | 23.5 | 13939.0 | 327566.5 | 48 | 7861596 | 21524 |
| 6 | 24.5 | 23.5 | 13939.0 | 327566.5 | 22 | 3603232 | 9865 |
| 7 | 24.5 | 23.5 | 13939.0 | 327566.5 | 10 | 1637833 | 4484 |

| | Female eggs per female per day mean | 90% maturity at year one* |
|---|---|---|
| Juveniles | 11.7 | 10.5 |
| Small adults | 199.2 | 199.2 |
| Large adults | 448.4 | 448.4 |

*Assuming that 90% of females mature at age 1 and that the batch fecundity is given by the formula: Batch = −1104 + 614*wt (Hunter et al. 1985).

Mortality rates of the late larval and early juvenile stages are unknown. We estimated these rates from the relationship of mortality rate to body size (Peterson and Wroblewski 1984) and adjusted them to achieve a stationary population. The relationship between dry weight and mortality rate is given by Peterson and Wroblewski (1984): $M_{(w)} = (1.92 \cdot y^{-1})w^{-0.25}$, and the relation between length and dry weight for northern anchovy is dry weight = 0.000488*SL^3.73, where SL is measured in cm (Butler 1987). For a 72.5-mm juvenile $M = 2.04$, and the daily rate is $z = 2.83/365.25 = 0.00557$. This value was adjusted to a "best" value of 0.0044 to obtain a lambda of 1.0. We chose the late juvenile stage for this adjustment because at present little is known about natural mortality in this stage.

TABLE 2

Stage-Specific Life-History Parameters of Northern Anchovy

Adult natural mortality rates are assumed to be constant with age and were derived from the stock synthesis model (Methot 1989). We also examined the effect of an annual fishing mortality rate of 0.6 on all adult stages. We derived adult growth rates from fisheries data (Fiedler et al. 1986).

### *Sardine Vital Rates*

Pacific sardine is also a multiple spawner. Batch fecundity estimates were based on MacGregor (1957) and Clark (1934). Little is known about the number of spawnings per year. Off Chile, the Pacific sardine (*S. sagax musica*) spawns every 7 days (Oliva et al. 1989), a rate similar to that of the northern anchovy. The South African pilchard, *Sardinops ocellatus*, spawns every 2–5 days, and older fish may spawn up to 80 times per year (Le Clus 1989). Fecundities in the life table (table 3) were estimated from batch fecundity times a total of 40 spawnings per year for the oldest age classes (the maximum rate is 80 spawnings per year, and the minimum is 24; table 4). We divided the daily fecundity by two to account for the number of female eggs.

We modeled the sardine population with thirteen stages as defined by Smith et al. (1992). The minimum, maximum, and mean daily instantaneous mortality rates and duration of each stage are derived from the literature (table 4). The durations of the egg and yolk-sac stages are derived from incubation experiments at different temperatures (Lasker 1964). Mean duration was derived from the development rate at 16°C, which is about the average temperature for sardine eggs (15.6°C; Butler 1987). We estimated mortality rates of yolk-sac and larval stages from the field (Butler 1991). The best estimates of egg mortality rates are from unpublished data (N. C. H. Lo). Durations of the larval and juvenile stages are from field studies of growth rates calculated from daily increments in the otoliths (Butler and Rojas de Mendiola 1985; Castillo et al. 1985; Butler 1987). The mortality rates of the late larvae through stage III juveniles are unknown. We estimated these rates from the general relation-

ship of mortality rate to body size (Peterson and Wroblewski 1984). The relationship between dry weight and length is given by: dry weight = 0.0122*SL^3.35, where standard length is measured in cm (Butler 1987). The predicted mortality rate was 0.0053 for stage I juveniles, and we adjusted this value to 0.0197 to achieve a theoretically stationary population. The mortality rates of stage IV juveniles and prerecruits are assumed to be the same as the mortality rates for northern anchovy of the same body size. Adult growth rates were derived from otolith readings (Phillips 1948); adult mortality rates were derived from the cohort analysis (Murphy 1966; MacCall 1979). Natural mortality was set at 0.4%$\cdot$y$^{-1}$. We also examined the effect of annual fishing mortality rates of 0.25 and 0.6.

## RESULTS

### *Anchovy*

Natural variations in individual stage-specific mortality or duration (table 5) result in changes of population growth from equilibrium to an annual increase or decrease of about threefold. The most influential stage appears to be the early larval. Natural variation in instantaneous mortality rates or duration of this stage lead to the largest changes in the population growth rate. The fastest growth rate of the early larvae results in a 278% increase in the population, whereas the slowest growth rate results in a 74% decrease (table 5). The least sensitive is the late adult stage: at that point, variations in growth and mortality have minimal effect on population growth. The sensitivity of the model to natural variations in fecundity may be an underestimate. The values in the literature are largely taken from biomass estimate studies, and none of these studies has encompassed a major environmental perturbation. There is some evidence that reproduction is drastically reduced during major El Niño events. Under such conditions the population declines rapidly.

We tested the effect of fishing on the anchovy population by using values of natural mortality of 0.76 and fishing mortality of 0.6 for both adult stages. Under these conditions the anchovy population declined at a rate of 5%$\cdot$y$^{-1}$.

### *Sardine*

The population growth rate of the Pacific sardine appears to be most sensitive to changes in egg and larval stages (table 6). Reported values for egg mortality vary widely in the literature (Smith 1973; Smith et al. 1989). Extremely high values of egg mortality—88% in the first day—were reported for the Pacific sardine off Peru (Smith et al. 1989). At this rate the model indicates that the population declines at the rate of 32% per year. The fastest growth of the early and late larval stages results in population growth rates of 43%$\cdot$y$^{-1}$, whereas the slowest growth rate of the early larval stage results in a population decrease of 28%$\cdot$y$^{-1}$ (table 6). The population is least sensitive to changes in the vital rates of the older stages, prerecruit through late adult.

Fishing affects the mortality rate of all adult sardine stages. If fishing mortality is 0.25, then the population declines at a rate of 18%$\cdot$y$^{-1}$. During the decline of the sardine fishery, fishing mortality was as high as 0.8 (Murphy 1966). At this level, the population declines at 50%$\cdot$y$^{-1}$. High fishing mortality reduces the abundance of the oldest age classes, which have the highest reproductive potential because of their larger size and greater number of spawnings.

## DISCUSSION

For the northern anchovy, natural variation in the duration of, and the instantaneous mortality rate of the early and late larval stage has the greatest effect on population growth (table 5). These results are similar to those of Smith (1985), who used a stage-based model to examine the role of vital rates in the dynamics of anchovy recruitment. Smith concluded that changes in the late larval stage have the greatest potential to affect survival and recruitment. Our results indicate that the anchovy population is also sensitive to changes in the early larval stage (table 5). The difference between our model and Smith's (1985) is largely due to the low mortality rate (0.16) that Smith used for this stage. The higher mean mortality rate (0.29) in our model leads to greater sensitivity, since faster or slower growth rates have a greater cumulative effect. High abundance of the early larval stage is a prerequisite to strong recruitment, but high larval abundance does not necessarily indicate strong year classes (Peterman et al. 1988).

In this model, we have also tried to examine the role of changes in fecundity. The variation in batch fecundity and spawning rate with age are well known, but little is known of interannual variability in the number of spawns per year. Estimated spawning rates for northern anchovy have varied from once every 6.25 days to once every 11 days. However, the Japanese anchovy, *Engraulis japonica*, spawns once every 1.4 days, and the Cape anchovy, *Engraulis capensis*, spawns as seldom as once every 16 days. Clearly, the number of spawns can vary significantly.

The sensitivity of the anchovy population matrix to changes in the vital rates of both early and late larvae is due to the dynamics of these stages. Natural mortality is high (Peterman et al. 1988), and the duration is long relative to egg stages. Changes in either value produce large effects. The observed natural variation in mortality rate of the early stage is quite large. Smith (1985) also identified the late larval stage of anchovy as important to recruitment variation. Variation in the duration of this stage is largely due to changes in temperature rather than difference in food densities (Methot and Kramer 1979; Owen et al. 1989).

Most life-table parameters do not change independently. The development rate of northern anchovy eggs and yolk-sac larvae is temperature-dependent (Zweifel and Lasker 1976, Lo 1986), as are larval growth rates (Methot and Kramer 1979). At about 22°C the egg, yolk-sac, and early larval stages would be brief. If all these stages are at their lower limits, the model population more than doubles each year. The population model can be stabilized if reproduction is restricted to the prerecruit stage (85–110 mm), with fecundity reduced to only 7 eggs per female per day. In other words, these life-history parameters are then similar to those of a small tropical anchovy, *Encrasicolina purpurea* (Clarke 1989; Somerton, in press).

From 1922 to 1942, temperatures at Scripps Pier averaged 17.1°C; from 1943 to 1974, temperatures averaged 16.6°C, excluding El Niño years 1957–59. The duration of both incubation and the yolk-sac stage are a function of temperature (Lasker 1964; Zweifel and Lasker 1976). Given these relationships, the Lefkovitch model, adjusted to stability at colder temperatures (11°C), predicts that the northern anchovy population would grow at an annual rate of 7% during warmer years (22°C), and that the sardine population would grow at $4\%\cdot y^{-1}$. Thus, temperature effects on the early stages alone cannot explain the difference in abundance of the two species from 1922 to 1942 and from 1943 to 1973. Temperature's effect on spawning rates in both species is unknown, as are its effects on the age of maturation and on the growth rate of juveniles.

The sardine population appears to be less sensitive to changes in vital rates than the anchovy population by an order of magnitude. Changing the duration of the early larval stage changes growth rates by $+40\%$ or $-27\%\cdot y^{-1}$. The addition of fishing mortality results in a $44\%\cdot y^{-1}$ decline in the population. Clark and Marr (1955) debated whether the environment or fishing caused the decline of the sardine population. Our results indicate that either the environment or fishing can produce these changes.

Some discussion of the assumptions of this model is warranted. The stage-specific model assumes that the population reaches a stable age distribution. In reality, stage-specific life-history parameters vary from year to year, and the population probably never achieves a stable age distribution. The fecundity estimates are averaged over all seasons and assumed to be constant on a daily basis. In reality, fecundity has a seasonal component, and most fecundity estimates are made during the peak season. It is also important to note that these fecundity estimates have been made during the course of biomass estimates and that few, if any, long-term studies exist. There is some indication that fecundity may be near zero during extreme environmental conditions (Csirke 1980; Ware and Tsukayama 1981).

The model also does not treat density-dependent effects. Growth rates predicted by the model are not sustained indefinitely in nature. Density-dependent effects on the population could be modeled by changing fecundity, mortality, or duration with population size. The model's sensitivity to changes in the larval stages suggests that cannibalism may be an important density-dependent feedback mechanism. Density-dependent influences are usually weak compared to density-independent factors, but MacCall (1981), Alheit (1987), Valdés et al. (1987), and Valdés Szeinfeld (1991) have indicated that cannibalism is an important density-dependent effect in clupeoid fishes. Cannibalism on eggs may, in fact, be largely density-independent (Smith et al. 1989), whereas cannibalism on larvae from different schools, because of the population's sensitivity to larval mortality rates, may be density-dependent.

## CONCLUSIONS

Natural variation in stage-specific vital rates can account for the large changes in population size observed in nature. The Lefkovitch model predicts changes in population growth that are as great as those indicated by the time series of these populations. Both populations are more sensitive to variation in the parameters of larval stages than to adult parameters. However, more research is needed on interannual variation of adult reproductive parameters, since these variations may have greater impact than indicated in the present model.

The sensitivity of the models to larval duration and mortality rate does not, however, indicate that these stages can be used to predict recruitment. Variance of postmetamorphic stages is sufficient to mask the relation between larval abundance and subsequent recruitment. These results are in accordance with those of Bradford (1992).

Many of these vital rates covary. Durations of both the egg and yolk-sac stages are temperature-dependent, and the maturation and spawning rates also vary with temperature. Changes in the ambient temperature could significantly change the life history of these species.

## Abstract

Six species presently dominate commercial fisheries for sharks off the western United States. The oldest of these fisheries (for soupfin shark, *Galeorhinus zyopterus* [=*galeus*]) was decimated in 1944 but has persisted for the past two decades on a small scale, averaging between 150,000 and 250,000 pounds (~68-114 MT) annually. The largest (for spiny dogfish, *Squalus acanthias*) has consistently produced landings in excess of 5 million lbs (~2273 MT) annually. The blue shark (*Prionace glauca*) fishery, in operation experimentally between 1979 and 1980, now is part of a long-line operation with markets still being explored. A drift gill net and experimental long-line fishery targets on common thresher shark (*Alopias vulpinus*) and shortfin mako shark (*Isurus oxyrinchus*). Declines in catches and size composition of the common thresher fishery have required serious management actions such as time/area closures, permit limitations, and low total allowable landings. The shortfin mako shark fishery has not seriously declined, but only takes one, two and sometimes three year old sharks. Landings of Pacific angel sharks (*Squatina californica*) in a localized bottom gill net fishery peaked in 1985 and 1986 at 1.2 million lbs (~546 MT) annually, but drastically declined due to decreased availability and alternative sources of low-cost, imported shark meat. The leopard shark (*Triakis semifasciata*), another common inshore species, is fished both recreationally and commercially, with its landings fluctuating between 18,000 and 100,000 lbs (~8-46 MT) per year, but no significant decline. Thus, total west coast shark landings increased steadily through 1985, but have since declined. Declines have occurred mainly because slow growth, low fecundity and late age at maturity make elasmobranchs vulnerable to overfishing.

## Introduction

Recent fisheries for elasmobranchs along the west coast of the United States began in the late 1970s and have continued to the present (Cailliet and Bedford 1983, Holts 1988). There were early warnings that these fisheries would most likely suffer from over- exploitation during early development (Holden 1974, 1977, Cailliet and Bedford 1983). The fisheries continued to expand until problems were very evident.

Elasmobranchs have low reproductive rates due to their low fecundity, slow growth rates, and late age of maturity (Holden 1974, 1977). These qualities, along with a natural inquisitiveness and lack of fear, make them vulnerable to overfishing (Anderson 1990, Compagno 1990). After the decline of the soupfin shark (*Galeorhinus zyopterus* [ = *G. galeus*, Eschmeyer et al. 1983]) fishery for vitamin A-rich liver oil in the 1940s, sharks were viewed as a resource of little value. In the late 1970s, popular interest in shark meat created new market demands. Domestic landings and imports of numerous shark species increased several fold during the last decade and have since declined (Holts 1988). Although the reasons for these variations are many, the most identifiable are market fluctuations and susceptibility of these stocks to over-exploitation.

It is now obvious that the management options taken were insufficient to prevent the predicted declines (Bedford 1987, Richards 1987, Holts 1988). Because of this, there is an increasing need for careful monitoring of exploited shark populations on the west coast to prevent stock depletion in these fisheries similar to actions now proposed for the east and gulf coasts of the United States (Hoff and Musick 1990). Two west coast shark species (common thresher, *Alopias vulpinus* and Pacific angel, *Squatina californica*) show signs of depletion and others are being harvested at near-record levels.

The purpose of this paper is to: 1) update the status of these fisheries, based upon catch data collected by the fisheries agencies for the three west-coast states and the United States National Marine Fisheries Service (National Oceanic and Atmospheric Administration); 2) describe current management strategies and regulations; and 3) propose ideas that can be used to effectively regulate elasmobranch fisheries.

### General Trends in West Coast Shark Fisheries

Shark landings along the west coast of the United States increased steadily through 1985, but have since declined (Table 1, Figure 1).

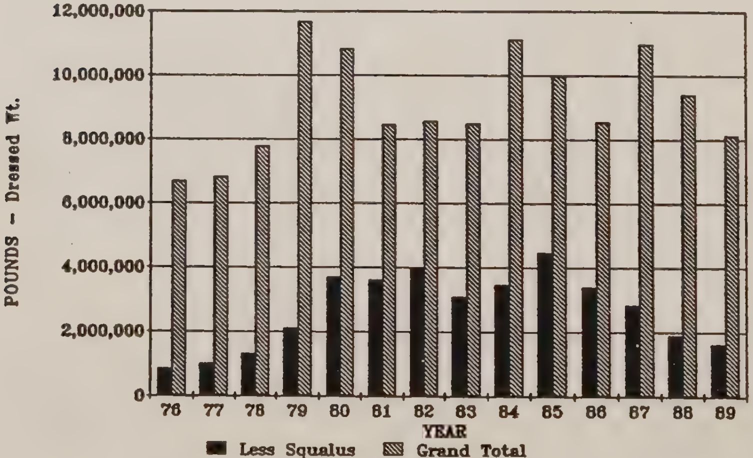

Fig. 1. Trends in annual west coast commercial shark landings ( in pounds, dressed weight) from 1976 through 1989.

Early landings were almost 7 million pounds (~3,180 Metric Tons) in 1976 and 1977, followed by later peaks at approximately 11 million lbs (~5,000 MT) in four different years (1979, 1980, 1984, and 1987).

Currently, landings are about 8 million pounds (~3,636 MT). For the entire coast, these trends closely followed those of the spiny dogfish (*Squalus acanthias*), which has consistently represented the largest portion of the shark catch. The next most

All weights are unloaded weights. Only the smoothhounds, horn and spiny dogfish are landed round weight. All others are market dressed in the field.

California shark catches, while most diverse, have shown a consistent decline in the last three years (Table 2). Landings in 1987 were 2.6 million lbs (~1,812 MT), dominated by Pacific angel, shortfin mako, and common thresher sharks. By 1989, the landings were down to 1.6 million lbs (~727 MT), and those of the common thresher dominated, with Pacific angel and shortfin mako shark catches showing significant declines. Due to the shortfin mako longline fishery, their landings subsequently increased. The soupfin shark catch has remained fairly consistent, but spiny dogfish, which were fairly common in 1987, had much lower catches during the next two years.

The commercial shark catches in Oregon were much less diverse and lower in abundance than those in California (Table 3). There has been a major decline from the 123,045 lbs (~56 MT) landed in 1987, dominated by the common thresher shark, to only 7,500 lbs (~3.4 MT) in 1989, dominated by soupfin sharks, mainly because Oregon cancelled their experimental fishery.

**Table 3. Oregon commercial shark landings (in pounds)**

| Species | 1989 | 1988 | 1987 |

| Unspecified, shark | 159 | 67 | 3,645 |
| Total sharks | 7,550 | 93,163 | 123,045 |

Off Washington there were only four species of sharks taken commercially, with the total annual catches remaining steady around 3.5 million lbs during the past three years (Table 4). Catches have always been dominated by spiny dogfish. The common thresher was commonly taken in 1987, but declined in the next two years.

## The Spiny Dogfish Fishery

The spiny dogfish is one of the most abundant sharks in temperate waters around the world, and it has been an important commercial species in many areas of the world (Ketchen 1986, Hanchet 1988, Holts 1988). Over the past 13 years, catches have gone through radical changes, especially in Canadian waters (Table 5). In the middle 1970s, there was virtually no catch of spiny dogfish north of Washington, but catches have steadily increased from 1983 to the present. This has been paralleled by relatively consistent catches in Washington, which have varied from a peak year 9.4 million lbs (~4,273 MT) in 1979 to 3.1 million pounds (~1,409 MT) in 1989. Catches from Canadian waters but landed in the United States have paralled those from Washington. The catches from Oregon and California have never amounted to much (Table 5).

**Table 5. Spiny dogfish landings (in pounds) in Washington, Oregon andCaliforniafrom 1976 through 1989.**

| 1977 | 5,428,652 | | 5,428,652 | | 384,177 | 5,812,829 |
| 1976 | 5,809,295 | | 5,809,295 | | 22,697 | 5,831,992 |

Historically, the spiny dogfish fishery has been subject to a "boom or bust" scenario (Anderson 1990). This may be due to its unique life history (Jones and Geen 1977; worldwide review in Hanchet 1988). It grows very slowly, lives a long time, has a very late age at first reproduction, low fecundity, and long gestation period, and is virtually absent from commercial fished areas for approximately the first 20 years of life. Without effort statistics, it is impossible to accurately depict what is happening to this population. However, it appears that it is commonly susceptible to overfishing, but that its longevity and absence from the fishery for much of its early life allows it to come back with vigor. Its present recovery is both a positive sign and a warning to carefully watch the north Pacific population.

## The Common Thresher Shark Fishery

The drift gill net fishery for common thresher sharks began developing off the southern California coast in the late 1970s. Market demand grew rapidly and the fishery was further stimulated by the more valuable by-catch of swordfish (*Xiphias gladius*) (Cailliet and Bedford 1983, Holts 1988). Despite several attempts to limit the fishery, it grew and expanded for several years. Swordfish became the primary target species and the number of vessels grew to over 200 by 1982. Each year after 1982 brought more northern expansion, first to Morro Bay, then Monterey and San Francisco, and ultimately to Oregon and Washington.

Common thresher shark landings peaked in 1982 at 2.4 million lbs (~1,091 MT, dressed weight) and then declined (Table 1, Figure 2). The coastwide fishery for this once abundant shark is now a thing of the past. It may be many years before stocks can support the demands of commercial exploitation.

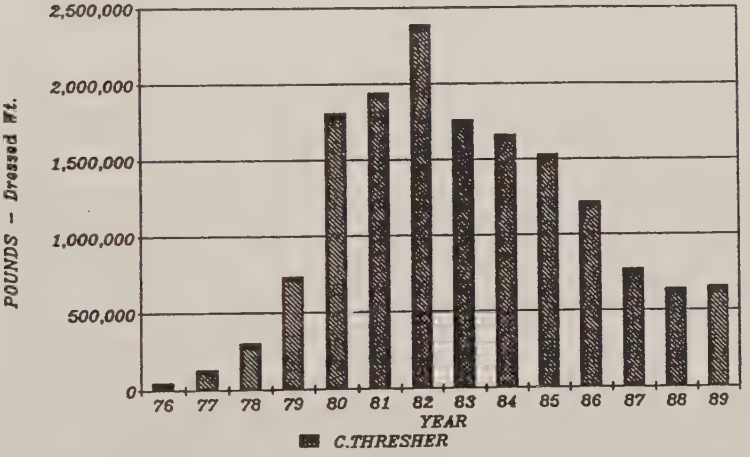

Fig. 2. Trends in annual west coast commercial common thresher (*Alopias vulpinus*) landings (in pounds, dressed weight) from 1976 through 1989.

Legislation passed in 1986 limited the directed common thresher shark fishery to 30 days during the month of May. Approximately 50 percent of the annual catch was taken during this period while the remainder was taken as a by-catch in the swordfish fishery during the fall and winter months. Small numbers of common thresher sharks were landed in Washington and Oregon during the mid-1980s, but declined drastically after 1988 (see Table 4). All directed fisheries for this species were terminated prior to the 1990 season and a tri-state management plan to limit the fishery was implemented in October, 1990. Common thresher sharks can still be taken and sold as a by-catch in the California drift gill net fishery for swordfish. While technically these sharks are not targetted during the swordfish season, nevertheless their landings are steady at about 0.6 million lbs (~273 MT) of one and two year old fish. However, only immature fish (averaging two years old) are taken (California Department of Fish and Game 1991).

### The Shortfin Mako Shark Fishery

Shortfin mako (=bonito) sharks were taken primarily as an incidental but valuable by-catch in the California drift gill net fishery for swordfish and thresher shark. Only a few individuals have ever been taken off Oregon and Washington. There are a couple of good reasons why the shortfin mako shark is, only now, becoming the primary target of a commercial longline fishery. Although readily marketable, they average only 34 lbs (~15.5 kg) dressed weight off southern California, compared to the 150 lb (~68 kg) average for common threshers in the late 1970s (Cailliet and Bedford 1983). Thus, the catch from both drift gill nets and longlines has been almost entirely composed of juveniles (one, two, and three year olds: California Department of Fish and Game 1991), although some mature adults were taken. As long as the threshers were plentiful, fishermen paid little attention to the shortfin mako.

Shortfin mako drift gill net catch rates peaked at 537,000 lbs (~244 MT) in 1982, and, following the common thresher shark fishery, declined to 215,000 lbs (~98 MT) by 1985 (Table 1, Figure 3). A few longline vessels began working the southern California Bight in 1986 and 1987. Landings increased but have subsequently declined to a level below 400,000 lbs (~182 MT). It took this entirely new fishing gear to create commercial interest in the shortfin mako shark.

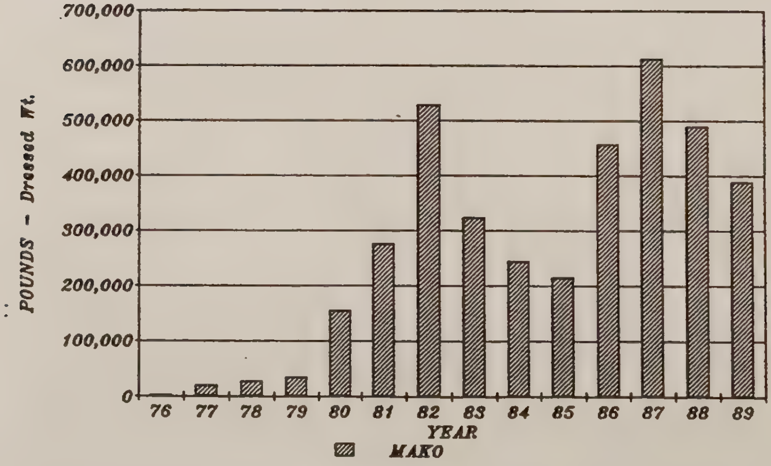

Fig. 3. Trends in annual west coast commercial bonito (= mako) shark *(Isurus oxyrinchus)* landings (in pounds, dressed weight) from 1976 through1989.

In 1988, the California Fish and Game Commission established an experimental, 10 vessel, longline shark fishery for shortfin mako and blue sharks. The gear is composed of a 3 to 4 mile (4.8 to 6.4 km) long stainless steel cable, to which leaders and baited hooks are attached. The entire cable is buoyed, at intervals of approximately 250-300 feet (75 to 90 m), so that the entire length of line remains in the near surface zone.

Continuation of this experimental fishery into 1990 required the most stringent regulations yet imposed on a shark fishery. These regulations stated that there will be: 1) only six (6) permits; 2) time/area closures away from sport fishing areas; 3) a total allowable landing quota set at 175,000 lbs (~80 MT); 4) a market developed to utilize the blue shark by-catch; and 5) a reduction of blue shark mortality. After three years, little progress has been made toward developing a market for blue shark. However, it has been demonstrated, beyond any doubt, that longlines are a potent gear for capturing mako sharks. During the first year of operation, the landings of approximately 240,000 pounds (~109 MT) were larger than the quota established later and equalled the entire "incidental catch," by the 250 vessel drift gill net fleet.

At some point during the mid-1980s, the shortfin mako shark captured the attention of the southern California sport fishing public as well. Surprisingly, prior to this time, little attention had been paid to it, even though these sharks have been long esteemed as game fish along the U.S. east coast. Between 1986 and 1989, estimates of the number of California angler trips for mako sharks grew ten fold, from 41,000 to over 410,000 trips annually. Commercial passenger fishing vessels ("party boats") now run shark fishing trips, on a regular basis, from nearly all southern California ports. The number of shortfin mako shark tournaments now takes second position, only to marlin tournaments, as southern California's most prestigious saltwater fishing event.

The experimental commercial long-line fishery was expected to continue on a year-to-year basis become California's first success at "resource stewardship" of an elasmobranch fishery. The 1990 season ended on September 30, 1990 with 175,000 lbs ((~80 MT) of shortfin mako shark landed. Blue shark mortality was reduced to near 22% and a small experimental market was established. In addition, the six permittees, in cooperation with the California Department of Fish and Game, reported tagging and releasing 600 shortfin mako sharks for distribution and abundance studies.

The shortfin mako shark population, like other oceanic sharks, is believed to be healthy, and relatively unexploited. Adults do not frequent California's coastal waters, and so are not subject to local fisheries. But a real threat to this shark population off California and elsewhere in the eastern Pacific lies in the potential for overexploitation by fisheries within the coastal "nursery" areas. This threat is particularly insidious, since the effect of over-fishing may not manifest itself for a number of years, until the missing juveniles would have themselves become the spawning stock. A sudden population collapse might follow. It appears that the lessons learned from the common thresher shark and others around the world inspired a far more conservative approach to this fishery's management, resulting in a denial by the California Fish and Game Commission for permits to continue the experimental drift longline fishery for shortfin mako sharks in 1992. In addition, in 1991 the Commission adopted specific bag limits (Section 27.60, Title 14, CCR) for the sport take of shortfin mako and five other species of sharks.

### The Blue Shark Fishery

Prior to the California experimental longline fishery, the only fishery directing effort at blue sharks occurred in 1979-1980 when one longline vessel fished for blue and shortfin mako sharks off southern California (Cailliet and Bedford 1983). The greatest source of fishing mortality for blue sharks occurred from their incidental capture during the developmental years of the drift gill net fishery off southern California. Preliminary annual mortality estimates were 15,000 to 20,000 sharks during that period. Changes in gear design and time-area closures reduced this incidental take, but there are no current mortality estimates for this fishery.

Only a portion of those taken by commercial fisheries are reported (Tables 1, 2, and 4), because there is virtually no commercial use yet developed for them, and most are discarded or used for fish meal. A small percentage of blue sharks are also taken in the set net fisheries for the Pacific angel shark and California halibut (*Paralichthys californicus*).

The current experimental longline fishery off southern California averages about four blue sharks for each shortfin mako shark. The fishermen in this fishery have reduced the incidental mortality of blue sharks through the development and use of a de-hooking tool (modified fence pliers) to remove the hooks from live sharks. Permittees are required to develop a market for the blue sharks not released in the by-catch. In 1989, 9,130 pounds (~4 MT) of blue shark were sold and an additional 43,000 pounds (~20 MT) sold in the 1990 season for jerky and for "fish and chips."

### The Angel Shark Set Net Fishery

A local fishery for angel sharks began developing in the Santa Barbara Channel during 1978 (Richards 1987). Initial marketing problems involved dressing the sharks at sea, which resulted in a 50% dressed landing weight of the live weight. There was an additional 50% loss at the fish market, with the net yield being 25-30%. The fishery expanded at an explosive rate as a result of more efficient processing procedures and new markets. These bottom dwelling sharks generally remain alive in the nets and small (< 42 inches or ~107 mm) individuals are returned to the sea in viable condition.

In 1985, the angel shark replaced the thresher shark as the principal food shark from southern California. Landings exceeded 1.2 million lbs (~546 MT) in both 1985 and 1986, but declined drastically by 1989 (Tables 1 and 2, Figure 4). This was a result of a combination of declining availability and alternative sources of low-cost imported shark meat.

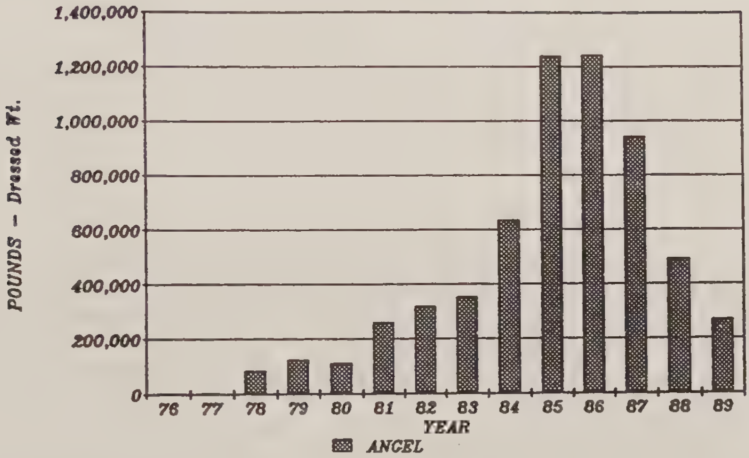

Fig. 4. Trends in annual west coast commercial angel shark (*Squatina californica*) landings (in pounds, dressed weight) from 1976 through 1989.

The most practical approach to take with this set net fishery was a minimum retention size limit, adopted in July 1988 (42 inches or 107 mm TL for females and 40 inches or 102 mm TL for males). Because the sharks caught are generally alive and hardy, release of undersized specimens would be a practical solution. Despite this management strategy, the continuation of a prosperous angel shark fishery did not occur. The major reasons for this include: 1) their lethargic and residental behavior; 2) their relatively low fecundity (Natanson and Cailliet 1986); 3) their apparently slow growth (Natanson and Cailliet 1990, Cailliet et al. 1992); 4) their demographic traits which make them susceptible to overfishing (Cailliet et al. 1992); and 5) the intensity of the set net fishery. However, as a result of Proposition 132, approved by California voters in 1990, set gill nets will not be allowed in nearshore waters, starting in 1994. Because fishermen must surrender their permits by 31 December 1993, this should effectively solve the problem of managing the Pacific angel shark fishery.

## The Soupfin Shark Fishery

More than 24 million lbs (~10,909 MT) of soupfin shark were landed from California waters in the eight years ending in 1944. This fishery decimated the soupfin population. A very small but consistent set net fishery for soupfin sharks has persisted over the past couple of decades. Landings in this fishery have roughly averaged between 150,000 and 250,000 lbs (68 to 114 MT: Table 1, Figure 5). It can be and has been a target for commercial fishermen, but is most often taken incidental to other commercial species.

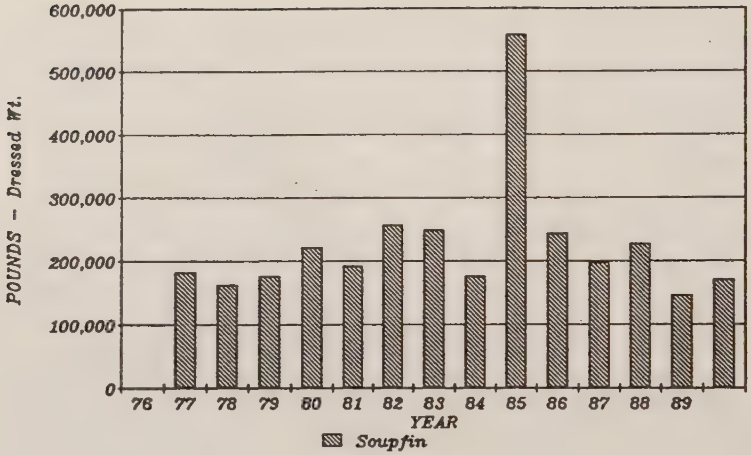

Fig. 5. Trends in annual west coast commercial soupfin shark *(Galeorhinus zyopterus [=galeus])* landings (in pounds, dressed weight) from 1977 through 1989.

## The Leopard Shark Fishery

The leopard shark (*Triakis semifasciata*), another common inshore species, is fished both recreationally, mainly by hook and line, and commercially, usually as a by-catch of other net fisheries (Smith and Abramson 1990). Its west coast landings have fluctuated from a low of 14,590 lbs (~7 MT) in 1976, to a high of over 100,000 lbs (~45 MT) in 1983 (Table 1, Figure 6).

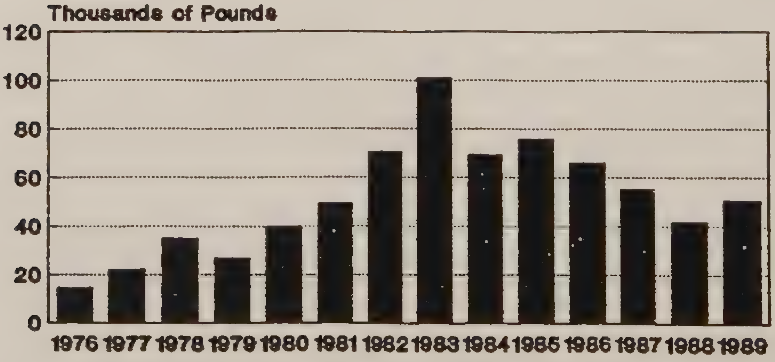

Fig. 6. Trends in annual west coast commercial leopard shark *(Triakis semifasciatus)* landings (in pounds, dressed weight) from 1977 through 1989.

Although there has been a general decline since then, there is no immediate reason for concern if growth, natural and fishing mortality, and demography estimates (Smith and Abramson 1990; Kusher et al. 1992; Cailliet 1992) are correct. Even so, the California Fish and Game Commission in 1991 adopted a minimum size (36 inches or 981 mm TL) and a bag limit (three per fisherman) for recreational anglers.

### Management Strategies for Elasmobranch Fisheries

It is a tragedy of unsound resource management that it took an obvious decline in fishing success for both common thresher and angel sharks in California to finally prompt the state to adopt serious regulations. Unfortunately, throughout the history of shark fisheries, this is a common mistake, repeated again and again. Resource managers need to understand more basically the unique limitations imposed by the life histories of sharks and rays, so they can convince those who make and enforce the regulations that such fisheries need to be seriously limited.

Several recent actions in California and the other western U.S. states are promising. The initiation of the experimental longline fishery in 1990 for shortfin mako and blue sharks was accompanied by the strict regulations already described, including a limited number of permits, time/area closures away from sport fishing areas, a landings quota, development of a market for the blue shark by-catch, and a reduction of blue shark mortality. The California Fish and Game Commission's authority to authorize experimental fisheries was given to it by the legislature and intended to develop new fisheries, either by gear or species target changes. Experimental fisheries were never intended to perpetuate limited commercial fisheries. At some point, each experiment is declared a success or failure. If it is characterized as a success, the legislature can authorize a new commercial fishery. As mentioned, the experimental longline fishery for shortfin mako sharks was closed in 1992.

Also, approval of Proposition 132 in November, 1990 will limit the use of set gill nets inside three miles of the California coast and will consequently affect the fisheries for (and thus landings of) soupfin, Pacific angel and leopard sharks. Common thresher, blue, shortfin mako, and soupfin sharks, caught by drift gill nets, will not be affected by this law.

Management options in general for elasmobranch fisheries include:

1) no restrictions at all (ultimately an economic solution);
2) limited entry of fishermen and vessels into the fishery;
3) size limits; 3) bag limits;
4) closed areas and/or seasons;
5) quotas;
6) gear restrictions; and/or
7) closure or total shutdown of the fishery.

All of these measures have advantages and disadvantages relative to the particular fisheries in question.

Having no restrictions at all leads to the rapid decline of most elasmobranch populations, resulting in a wide-scale decimation of some major predator populations and possibly altering the ecosystems in which they operate. This option, although apparently the one most often used, is not a viable alternative.

Limited entry is a viable option if the fishery has not already developed a large fleet. Unfortunately, once the threat to a fishery is evident, it is usually too late to limit the number of fishermen or vessels allowed to use the resource. This approach is costly, both monetarily and legally, and should be considered only if all other possible approaches prove ineffective.

Size limits are valuable in that they can influence the age at entry into fishery, and thus have a major impact on the proportion of reproductively viable individuals subject to fishing mortality. This approach requires valid life history information such as age (Cailliet 1990, Cailliet et al. 1986), growth (Cailliet and Tanaka 1990), age composition, age-specific mortality, age-at-maturity, and age-specific natality (Pratt and Otake, 1990), which often provides demographic information (Cailliet 1992, Cailliet et al. 1992). These approaches are often costly and have not been used on many elasmobranch species, mainly because the life history information is unavailable (Cailliet 1990). Also, some gears (i.e. drift gill nets) do not allow for the live release of undersized fish.

However, with this information, fishery regulations can insure, either via logistic, dynamic pool, or demographic models (Hoenig and Gruber 1990), the continued stable existence of a fished stock. Unfortunately, this approach has only been used on a few elasmobranchs which support fisheries (Jones and Geen 1977, Grant et al. 1979, Ketchen 1986, Anderson 1990, Smith and Abramson 1990, Cailliet 1992, Cailliet et al. 1992).

Catch limits basically are strongly tied to the number of fishermen utilizing the resource. This approach also requires detailed life history information, especially good estimates of population size, and therefore can be expensive. It is very difficult to enforce and is used primarily in sport fisheries. In fact, as mentioned earlier, the California Fish and Game Commission in 1991 adopted specific bag limits for the sport take of shortfin mako, along with thresher, soupfin, sixgill (*Hexanchus griseus*), sevengill (*Notorhynchus cepedianus*) and leopard sharks.

Closed areas and seasons have been used with some success in California shark fisheries (Bedford 1987, Richards 1987, Holts 1988). This is usually the most successful when movement patterns or important life processes (reproduction, spawning, larval or juvenile growth, feeding, etc.) occur in a specific place at a specific time, and the fishery can be directed away from these. In most cases, however, these details are not well known for elasmobranch fishes subject to fishing pressure.

Quotas are another management approach and these have been used in only one shark fishery, the shortfin mako, in which a new gear was being used and evaluated. It is too early to determine whether this approach has been successful. To set quotas, a great deal of knowledge of the life history of the species involved is required. This approach has been used extensively for northeast Pacific fisheries to regulate groundfish catches. It often involves some equation, based upon maximum or optimum sustainable yield (MSY or OSY) estimates from extensive catch data collection and analysis, which leads to the total allowable catch (TAC) and can be revised from year to year, depending on future catch statistics. The use of fisheries models on elasmobranch populations is reviewed by Anderson (1990).

The final two approaches, gear restrictions and closure or shutdown of a fishery, may be the only viable one for some elasmobranch fisheries. It is hoped, however, that intelligent data gathering and decision making will occur prior to implementating these radical solutions.

### Acknowledgements

This paper is the result of a long-standing relationship among the authors in which there is a continual exchange of information between those involved in doing basic research on elasmobranch fishes and those involved in monitoring the catches and suggesting solutions to problems. Linda K. Martin, Mary Nishimoto, Diana Watters, and Mary Yoklavich read the manuscript, provided comments, and helped with graphics. We wish to thank John West for his invitation to present this information at the Sharks Down Under conference, sponsored by the Taronga Zoo in Sydney, Australia. The work represented in this review was partially the result of research sponsored by the National Oceanic and Atmospheric Administration, National Sea Grant College Program, Department of Commerce, under grant numbers R/F-81 and R/5-84 through the California Sea Grant College Program, and in part by the California State Resources Agency, project numbers R/F-81 and R/F-84. The U. S. Government is authorized to produce and distribute reprints for governmental purposes.

# EFFECTS OF THE STIPE-BORING AMPHIPOD *PERAMPHITHOE STYPOTRUPETES* (COROPHIOIDEA: AMPITHOIDAE) AND GRAZING GASTROPODS ON THE KELP *LAMINARIA SETCHELLII*

*J. R. Chess*

## ABSTRACT

The ampithoid amphipod *Peramphithoe stypotrupetes* hollows and infests the stipes of the alga *Laminaria setchellii* after intense grazing of its lamina by gastropods. The intensity of gastropod grazing and subsequent levels of amphipod infestation appear to be correlated with calm ocean conditions. Once established in the stipe, a pair of adult amphipods produces multiple cohorts of offspring, which hollow and kill the plant. At a study site off northern California, an entire bed of the alga was infested and no plants survived. Aspects of the natural history of *P. stypotrupetes* are discussed.

Invertebrates that graze on the mature sporophytes of large brown algae (kelps) generally cause only minor damage to the plants (Foster and Schiel, 1985), but there are exceptions. The decimation of kelp forests by echinoids has been well documented (e.g., Lawrence, 1975; Chapman, 1981), but many of these occurrences are believed to be unnatural events that are the result of population explosions stimulated by coastal pollution or the lack of natural predators (North and Pearse, 1970; Estes and Palmisano, 1974; Kain, 1979). Natural population levels of sea urchins commonly have little effect on mature, attached kelp, since the urchins feed mostly on drift material (Foster and Schiel, 1985).

A number of mollusks and crustaceans are known to feed on kelps, but generally they are nonlethal. The European acmaeid *Patina pellucida* (L.) can graze and weaken the holdfast of *Laminaria hyperborea* (Gunn.) Foslie (see Kain, 1963), and the Californian trochids (*Tegula* spp.) can damage kelp lamina when numerous (Foster and Schiel, 1985; personal observation). Other gastropods are damaging only when in abnormally high densities, as, for example, *Lacuna vincta* (Montagu), which can markedly deplete stands of *Laminaria saccharina* (L.) (see Fralick *et al.*, 1974). Crustaceans that burrow into stipes and holdfasts of kelp, usually with nonlethal effects, include the isopods *Limnoria algarum* Menzies and the amphipod *Ampitholina cuniculus* (Stebbing), as well as members of the amphipod families Biancolinidae, Najnidae, Phliantidae, and Eophliantidae (Menzies, 1957; Myers, 1974; Conlan and Chess, 1992).

Members of the herbivorous corophioidean amphipod family Ampithoidae inhabit self-constructed tubes or chambers in coastal marine algae (Conlan and Bousfield, 1982). Among these, certain species of *Peramphithoe* have developed a partially close relationship with brown algae of the order Laminariales on which they live and feed. *Peramphithoe humeralis* (Stimpson) in the northeastern Pacific and *P. femorata* (Krøyer) in the southeastern Pacific both inhabit *Macrocystis pyrifera* (L.), where they fold and stitch (glue) lamina margins into chambers (Limbaugh, 1955; Kreibolm de Paternoster and Escofet, 1976). Although these species graze the lamina, they are not fatal to the plants.

In the northeastern Pacific, *Peramphithoe stypotrupetes* Conlan and Chess hollows and inhabits the stipes of *Eisenia arborea* Areschoug and *Laminaria setchellii* (see Conlan and Chess, 1992: *L. setchellii* Silva as *L. dentigera* Kjellman). This relationship appears to be unique, in that the alga is almost always destroyed, the destruction sometimes involving entire beds. The amphipod feeds on the medullary and cortical tissues of stipes, forming a hollowed chamber where a pair of adults, and their successive broods, feed and grow, eventually causing the death of the plant (Conlan and Chess, 1992). This report describes how *P. stypotrupetes* infests *L. setchellii*, documents its impact, and presents additional natural history observations to those reported in Conlan and Chess (1992).

## Study Areas

Observations and collections were made irregularly between 1972 and 1992 during other investigations along the Mendocino coast of northern California (39°21′N, 123°50′W), Baranof Island (56°03′N, 134°20′W), southeastern Alaska, and off Santa Catalina Island (33°28′N, 118°29′W), southern California. Directed studies on the infestation by *Peramphithoe stypotrupetes* and attrition rates of *Laminaria setchellii* were made at Pt. Cabrillo on the Mendocino coast between November 1978 and April 1981, but other observations came from the various sites along that coast throughout the 20-year period.

Pt. Cabrillo, a state biological preserve, is an exposed rock headland with surge channels 3–20 m in depth that are semi-protected from moderate seas by offshore reefs and exposed rocks. The fauna and flora are typical of a northern California wave-swept habitat, with the most conspicuous kelps being *Postelsia palmaeformis* Ruprecht and *Lessoniopsis littoralis* (Tilden) in the intertidal, *Laminaria setchellii* from the lower intertidal to about 10-m depth, and *Pterygophora californica* Ruprecht and *Nereocystis leutkeana* Mertens growing from depths of about 8–15 m. The area observed encompassed approximately 1,200 $m^2$.

## Incidental Observations

The association between *Peramphithoe stypotrupetes* and kelps was first recognized in 1972 at Santa Catalina Island, where abraded stipes of *Eisenia arborea* were collected and noted to contain numerous ampithoid amphipods. The same condition was observed in the stipes of *Laminaria setchellii* in northern California in 1977, and in Alaska during 1980.

Successful stipe infestation by the amphipods appeared to depend upon initial intense grazing by other invertebrates on lamina tissues and to some extent the transition zone (the main region of active cell division, located between the stipe and lamina). If the meristem in the transition zone is destroyed, then the plant is incapable of further growth and dies (Kain, 1971).

Along the Mendocino coast, infested stipes were conspicuous during most years. However, the highest rates of infestation appeared to coincide with years of exceptionally calm fall and winter months. Observations during these calm periods revealed an unusually high degree of grazing on the lamina of *L. setchellii* by benthic herbivores, primarily gastropods (Fig. 1). The grazers concentrated on the perennial kelps during the winter months when ephemeral algae were scarce or absent. The trochid gastropods *Tegula pulligo* (Gmelin), and, to a lesser extent *Calliostoma ligatum* (Gould), were the most prominent grazers during daylight hours. At night, other molluscan grazers became active, as evidenced by observations made in a quiet cove (Little River) about 8 km south of Pt. Cabrillo in March 1984. There, about two h after sunset, the trochids on the stipes and lamina of *L. setchellii* and *Pterygophora californica* were joined by several diurnally sedentary grazers, including the abalones *Haliotis rufescens* Swainson and *H. walallensis* Stearns and the chiton *Cryptochiton stelleri* (Middendorff).

These grazing molluscs appear to have limits to their ability to maintain a footing on stipes that are whipped by surge. It was noted that, under conditions of moderate surge (seas 1.5–2.0 m), trochids were absent from *L. setchellii* at depths shallower than about 7 m, but were present on those in adjacent sites at depths of 12–15 m. Under conditions of heavy surge, these gastropods appeared unable to maintain their position on stipe tips or lamina at any depth.

On the Mendocino coast, annual transition-zone expansion and lamina growth begins during late February and early March. Growth proceeds in the manner typical of other species of *Laminaria,* where "As the new lamina enlarges, the old one becomes a mere appendage at its apex and ultimately breaks off completely" (Fritsch, 1945, p. 195).

During early March (1992) at Mendocino, many *Tegula pulligo* and *Calliostoma ligatum* were observed feeding on the old lamina tissue, but not on the adjacent new growth of expanding lamina tissue (Fig. 2). This suggests that snail-induced damage to the transition zone takes place before the new growth begins, and that the damage is probably not lethal to the plant.

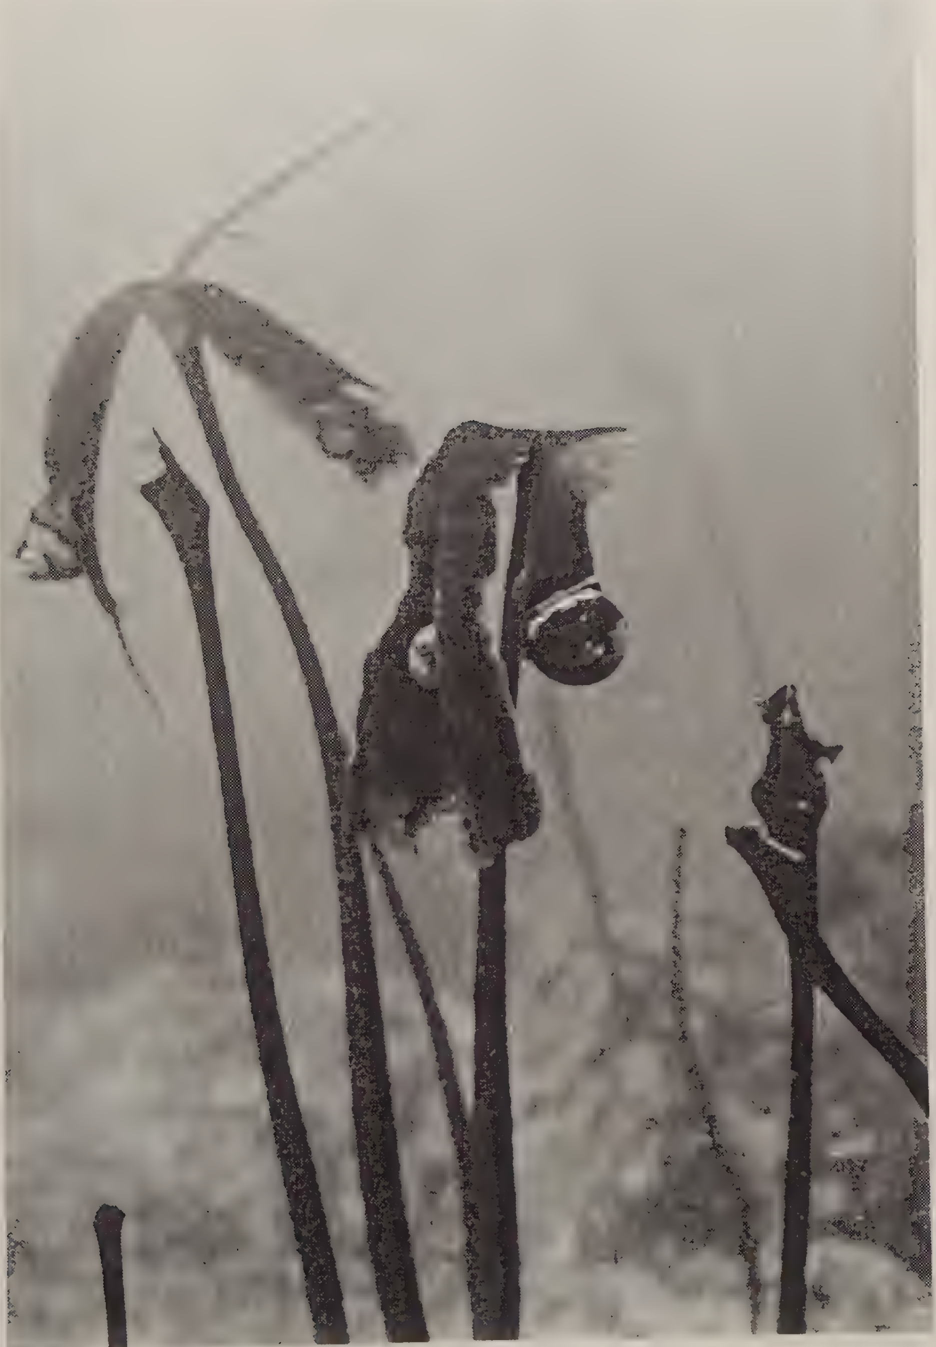

Fig. 1. *Tegula pulligo* grazing the lamina of *Laminaria setchellii* during a calm winter period (December).

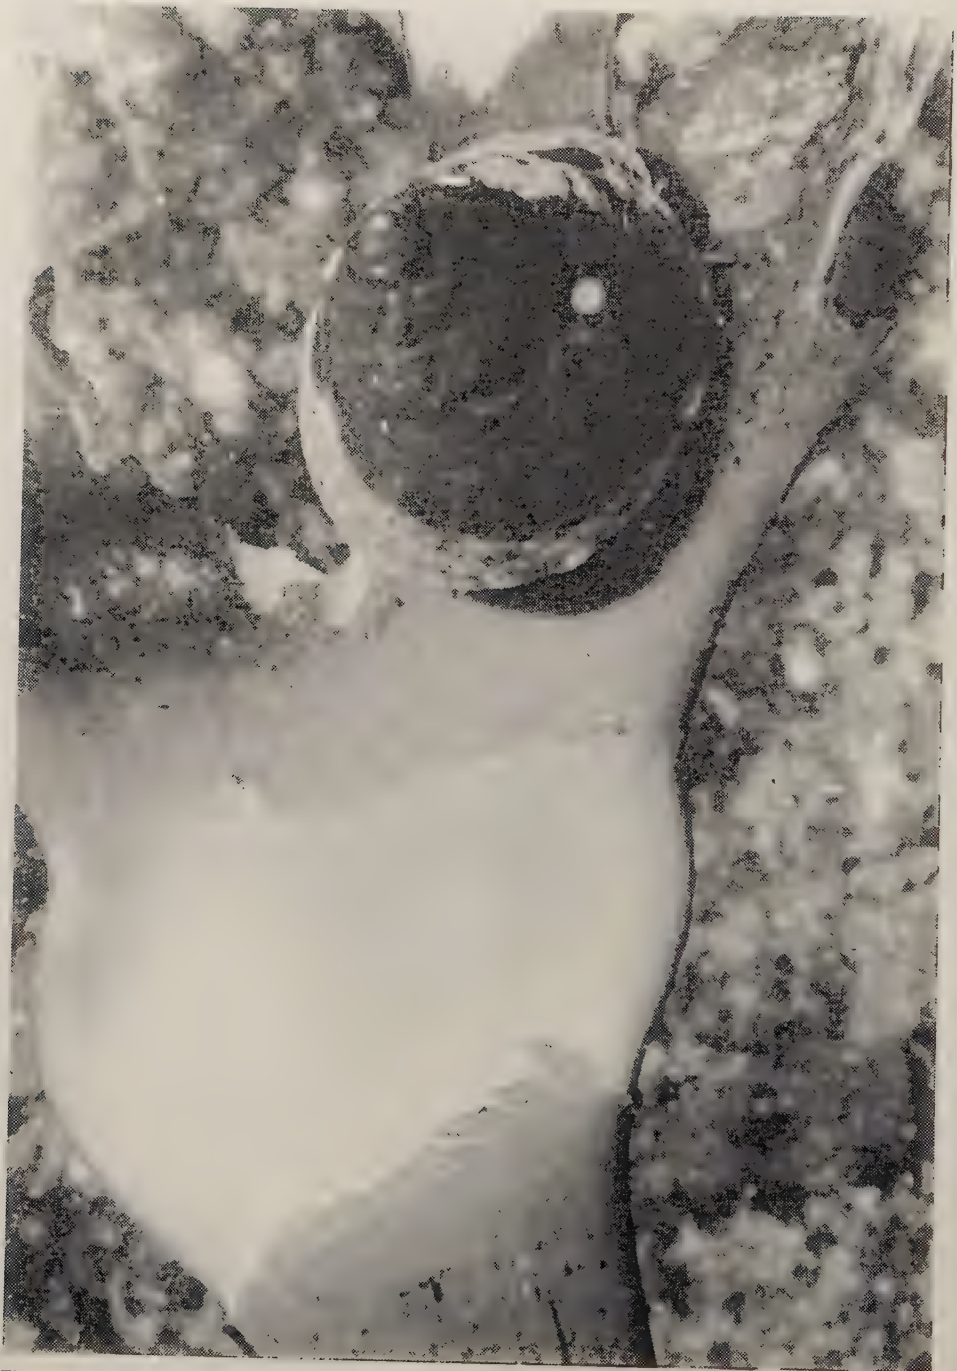

Fig. 2. Expanding new lamina (light area) in *Laminaria setchellii* with *Tegula pulligo* feeding on old lamina tissue during early spring (March).

All infestations of *L. setchellii* by *P. stypotrupetes* occurred on stipes that had lost lamina. However, stipes with the gastropod *T. pulligo* still attached often were grazed into the distal areas of the transition zone, whereas those abraded by physical forces retained at least a remnant of lamina and an intact transition zone. It appeared that only the gastropod grazers removed entire lamina, thus exposing stipe tissues to amphipod infestation.

## MATERIALS AND METHODS

Directed observations and measurements of the effects of *P. stypotrupetes* on *L. setchellii* were initiated at the Pt. Cabrillo site during 1978, and monitored irregularly until 1981. This site was assessed occasionally during the following years.

All field observations and collections were made using scuba or snorkel. At Pt. Cabrillo, individual plants of *L. setchellii* were marked with numbered disc tags in order to determine rates of infestation by the amphipod and stipe longevity after infestation. Stipes were measured (to the nearest 0.5 cm) from the base of the holdfast to the distal tip of the stipe. Collections of amphipods were made by severing infested stipes near the base, placing each stipe in a separate plastic bag and sealing with rubber bands.

## RESULTS

### Infestation by the Amphipod

During the fall and winter of 1978–1979 infestations became rampant when particularly calm ocean conditions prevailed from September through April.

*Laminaria setchellii* occurring in the shallowest depths appeared considerably healthier and less infested with the amphipod than those at greater depths. This relationship was measured during August 1980 at Pt. Cabrillo, when infested and healthy plants were tallied within depth-stratified, adjacent 1 × 25-m belt transects at depths of 1–2 m, 2–3 m, and 3–4 m on a vertical face of a deep surge channel. Within the shallow belt, 5 of 386 stipes (1.3%) were infested, and within the middepth, 12 of 54 (22.2%) were infested. In the deepest belt, only 2 bored-out stipe stumps and no intact plants were found.

Two groups of healthy, uninfested plants were tagged to determine rates of infestation. One group of 14 stipes (on an isolated boulder at a depth of 3 m) was tagged on 16 November 1978. Seven months later, one stipe was infested and five others were missing. After another 14 months, four more plants were infested, and the one infested earlier was a mere stump. Thus, after 21 months, only four of the original 14 plants remained uninfested. A group of 29 stipes in a surge channel at 2–4-m depth was tagged on 3 July 1979. Fourteen months later all 11 that remained were infested, and after another eight months no remnants of these plants remained. During subsequent observations in 1983 and 1985, no *L. setchellii* could be found in the study area, and by 1990 only a few plants with approximately 1-cm diameter stipes were present.

Throughout the study period, infested stipes were common and sometimes abundant at other sites along the Mendocino coast, but nowhere was the destruction of *L. setchellii* as severe as that observed at Pt. Cabrillo.

### Deterioration of Infested Stipes

Individual stipes varied considerably in their degree of infestation or deterioration. The most recently infested contained only one or two adult amphipods in excavations only a few cm deep, while adjacent stipes, apparently infested earlier, were severely damaged with tattered tips and perforations through the outer wall (Fig. 3). It was impossible to determine the number of amphipods in residence or the depth of the excavations in the more severely damaged stipes without dissecting them. However, as noted earlier (Conlan and Chess, 1992), the larger stipes with large chambers generally contained the most amphipods (Fig. 3). Nine of 11 infested stipes, tagged and measured along with the 14 healthy plants during November 1978, persisted for seven months before being remeasured in June 1979. Initially these plants varied in length from 33–55 cm ($\bar{x} = 46.3$ cm) and during the period were reduced to between 6 and 41 cm ($\bar{x} = 22.8$ cm), a mean rate of stipe reduction of 3.01 cm/month. The largest of the infested stipes (55 cm) was reduced at the greatest rate (6.71 cm/month), and the smallest at the lowest rate (1.10 cm/month), but this relation did not hold with intermediate-sized plants. The deterioration rate of the second (surge channel) group of stipes was not calculated, because it was not known when they had become infested.

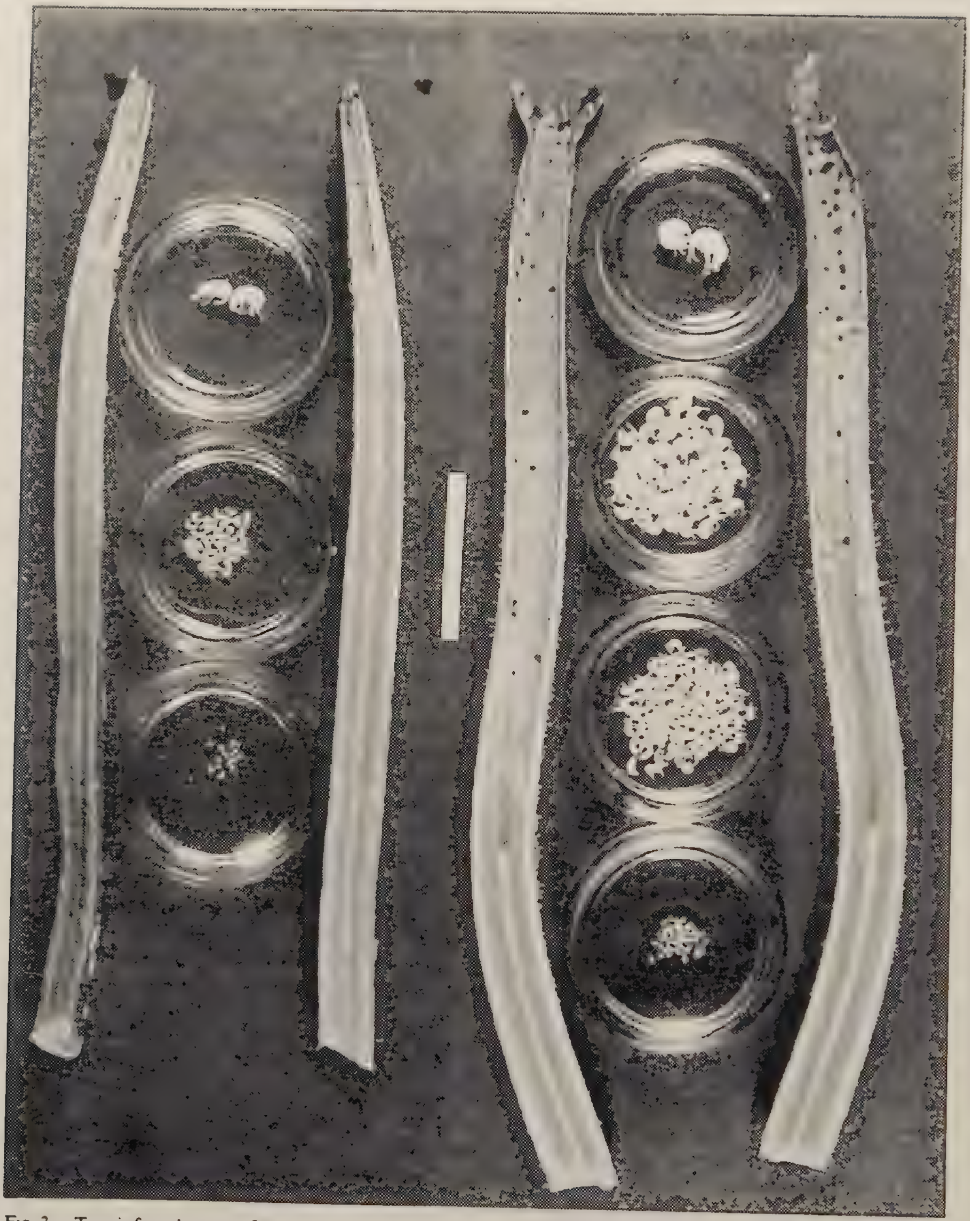

Fig. 3. Two infested stipes of *Laminaria setchellii*, the larger with lateral perforations, each with its complement of adults and offspring cohorts of *Peramphithoe stypotrupetes*, both collected 27 February 1992. (Scale bar = 5 cm; small chamber 6 cm long, larger 24 cm.)

## Amphipod Reproduction Within Stipe Chambers

Brooding females were found within infested stipes during all seasons. The size of brood or number of offspring within cohorts was variable, with the largest females tending to have the most and the smallest the fewest. Fecundity of females 20–24 mm in length ($N = 3$) was 85–145, $\bar{x} = 111.0$; among those 16–19 mm ($N = 8$) was 30–120, $\bar{x} = 69.0$; and from those 14–15 mm ($N = 2$) was 33–60, $\bar{x} = 46.5$. The smallest brooding female found was 14 mm. There appeared to be some mortality or loss of members of any cohort, as suggested by the numerical composition of those found in the large stipe of Fig. 3. Here, the number of offspring in three cohorts of a 19-mm female and 18-mm male were: 62 individuals in the 1.7–2.0-mm cohort, 94 at 5.5–7.0 mm; and 58 at 9–11 mm. The mother was carrying 120 embryos.

The number of cohorts cohabiting a chamber was positively correlated with the length of the hollowed stipe chamber. Offspring cohorts in chambers 2–4-cm long ($N = 7$) varied from zero–one, $\bar{x} = 0.29$; those from 5–10-cm chambers ($N = 13$) varied from zero–3, $\bar{x} = 1.23$. All chambers from 15–25 cm ($N = 5$) contained four cohorts, and the largest chamber observed, 116 cm, contained four or possibly five. Separating large individuals into cohorts was often difficult, because older amphipods appear to grow at a slower rate and their size groupings become more obscure. When the cohort size-classes were easily distinguished, the smallest were always found in the lowermost part of the chamber.

Several stipes that were variably hollowed out and decomposing contained no amphipods, and others that had been reduced to mere stumps (<10 cm high) often harbored only a few *P. stypotrupetes* of mixed sizes, and at times other species of gammarideans as well.

## Discussion

*Peramphithoe stypotrupetes* appears to be one of the few crustaceans known to be capable of large-scale killing of mature kelp sporophytes. However, other gammaridean amphipods, primarily *Peramphithoe humeralis*, have been described inflicting considerable damage to large areas of a forest of *Macrocystis pyrifera* off San Diego following a period of elevated sea temperatures (Tegner and Dayton, 1987). *Amphitholina cuniculus* burrows into the medullary region of the stipes of *Alaria esculenta* off Ireland (Myers, 1974). It was reported to have infested up to 82% of a bed of *A. esculenta* with a large proportion "so badly damaged . . . that it was unlikely that the alga would survive the winter" (Lewis, in Myers, 1974, p. 469). *Amphitholina cuniculus,* which is morphologically highly modified for burrowing (Conlan and Chess, 1992), enters the stipe laterally rather than through an abraded or grazed distal end as does *P. stypotrupetes* (see Myers, 1974).

### Conditions for Infestation

The relationship between increased grazing by gastropods on off-bottom kelp lamina and low water turbulence is probably wide spread. The brown sea hare *Aplysia californica* Cooper has been seen on the tops of *Pterygophora californica* when seas were calm (Foster and Schiel, 1985), and a one-day period of heavy surge dislodged all *Norrisia norrisi* Sowerby and *Tegula aureotincta* Forbes from the upper portions of plants of *M. pyrifera* (see Bakus, unpublished, cited in Lowry *et al.*, 1974). Surge from wave action is considered to be maximal in the subtidal fringe and to decrease gradually with depth, and the vertical distribution of many organisms is determined chiefly by these forces (Kitching, 1941). The reported observations thus indicate that less turbulent conditions in deeper water have allowed more intense gastropod grazing pressure on *L. setchellii,* and subsequently higher levels of infestation by *P. stypotrupetes,* than for plants at shallower depths. The extended period of calm ocean conditions during the fall and winter of 1978–1979, with intense gastropod grazing even at shallow depths, was probably the primary cause of the high level of stipe infestation and subsequent decline of the populations of *L. setchellii* at Pt. Cabrillo.

The relative tenderness of lamina tissue, as compared to the stipe and holdfast, may account for its apparent preference by grazing gastropods. Steinberg (1985) suggested that "stipes and holdfasts . . . are often much tougher than the blades of the same plant and that many herbivores, including *Tegula,* probably find it physically very difficult to consume these plant parts."

The avoidance of the newly expanding transition zones and laminae by gastropod grazers observed during March 1992 suggests that these tissues may produce higher levels of herbivore-deterrent chemicals than the older, degraded lamina. In studies of food preference, species of phaeophytes with high levels of phenolic compounds were avoided by *Tegula funebralis* (A. Adams), while those with low levels were preferred (Steinberg, 1985). In other studies, it was found that the young growing tips and reproductive structures of tropical green algae contained higher concentrations of noxious compounds than mature plant tissues (Paul and Fenical, 1986; Paul and Van Alstyne, 1988). A similar condition may exist with the new spring growth in *Laminaria*. It is also possible that trochid gastropods are incapable of maintaining a footing on the slippery new surfaces. Kain (1971) suggested that this "highly mucilaginous surface is not a very hospitable substratum for most organisms."

Avoidance of the new growth by gastropods suggests that whatever damage they cause to the lamina and distal transition zone must occur prior to new growth during the fall and winter months. Therefore, it seems unlikely that *P. stypotrupetes* could successfully invade stipes of *L. setchellii* during early spring and summer, when rapid lamina growth is in progress.

### Amphipod Infestation

The infestation of only those stipes of *L. setchellii* that have been previously grazed to or into the transition zone indicates that *P. stypotrupetes* is probably incapable of penetrating, or possibly using, the tissues of the lamina or outer stipe. The amphipod is, however, capable of entering and using the tissues of the transition zone and inner stipe, as the gut contents showed (Conlan and Chess, 1992).

In the Monterey Bay area, an ampithoid gammaridean, probably referable to *P. stypotrupetes,* was described as burrowing into the sides of stipes of *Pterygophora californica* (much as *Amphitholina cuniculus* enters *Alaria esculenta* (L.)), hollowing a chamber in the interior and producing successive broods of offspring. Mortality to these plants occurred when surge-induced turbulence broke the stipe off at the area of the chamber. Infestation levels were described as variable, at times as high as 20%, but at other times none could be found (Michael Foster, Moss Landing Marine Laboratories, personal communication, 24 March 1992). Schroeter (cited in Conlan and Chess, 1992) found this same relationship occurring off the coast of Santa Barbara. Although *P. californica* is a major component of the sublittoral off the Mendocino coast, there was no evidence of it being infested there, but it could easily have been overlooked if infestations occur infrequently or at low levels.

Hollowing of stipes of *Laminaria setchellii* by *Peramphithoe stypotrupetes* and the subsequent rate of stipe shortening undoubtedly accelerates with the development, growth, and increased feeding of successive broods. The mean rate of shortening (3.01 cm/month) would be much lower during initial infestation and much higher during later stages, the rate probably being proportional to the cumulative biomass of amphipods occupying a chamber.

The tendency for the crowded amphipods to perforate the distal portions of stipe chambers would allow increased water circulation inside, and thus enhance respiration and waste removal. It is unknown if the perforations are formed specifically or are simply the result of heavy grazing on the interior of the stipe. In either case, lateral stipe perforations would seem beneficial to amphipods occurring in high densities. However, the loss of a fraction of newly hatched juveniles, suggested above, may be proportional to the number of perforations present. On the other hand, the strong tendency of offspring cohorts to segregate by size (the smallest occurring deepest in the chambers where there are no perforations) must offset their potential loss.

The circumstances that stimulate the amphipod's abandonment of stipes is unknown, but is most likely related to the lack of available food, when the inner stipe tissues are gone, or to the noxious environment of the chamber when the remaining tissues begin to decompose. The length of time for the death of stipe tissue to occur and for decomposition to begin seems quite long, since actively infested stipes persisted for at least 223 days.

It appears that, for high levels of infestation to occur, extended periods of calm ocean conditions, coupled with extensive lamina grazing by gastropods, are required to permit the invasion of stipes by *Peramphithoe stypotrupetes.* At Pt. Cabrillo the infestation of stipes seemed to increase nearly exponentially during the 1978–1980 period. This was probably caused by rapid infestation of neighboring stipes by offspring of the initial invaders.

The original shallow-water community of *Laminaria* at Pt. Cabrillo was dramatically modified by the mortalities caused by the gastropod—*P. stypotrupetes* invasion. Although there have been subsequent low levels of recruitment, *L. setchellii* remains a minor component of the biota there after 12 years. However, at various sites in the vicinity of Pt. Cabrillo, *L. setchellii* is abundant and luxuriant. The situation at Pt. Cabrillo may be explained by its being a biological preserve where unusually high densities of the red abalone *Haliotis rufescens* occur. Although this abalone relies primarily on drift algae for nutrition (Leighton, 1971), intense grazing by these herbivores has probably precluded the reestablishment of *L. setchellii*. Even though plants of *L. setchellii* were virtually eliminated at Pt. Cabrillo, *P. stypotrupetes* appears to have little lasting effect on the structure of algal communities over time.

## ACKNOWLEDGEMENTS

I am grateful to Daniel Howard, Southwest Fisheries Science Center Tiburon Laboratory, National Marine Fisheries Service, for help in the field and discussion of these observations. For constructive criticism of the manuscript, I thank Edmund S. Hobson, Kathleen E. Conlan, and Michael S. Foster.

# Comparison of age at sexual maturity and other reproductive parameters for two stocks of spotted dolphin, *Stenella attenuata*

**Susan J. Chivers**

P.O. Box 271, La Jolla, CA 92038-0271

**Abstract.**–We examined the average age at attainment of sexual maturity (ASM) and several other reproductive parameters for evidence of density compensatory responses in two stocks of the spotted dolphin, *Stenella attenuata*. The northern offshore and southern offshore stocks were compared because both have been exploited by the yellowfin tuna purse-seine fishery, but at different rates. We predicted decreasing trends in the ASM and increasing trends in the pregnancy rate for each stock because both have declined in abundance. A lower ASM and a higher pregnancy rate were predicted for the sample from the northern offshore stock because it has been exploited to a greater extent than the southern offshore stock. No statistically significant trends were found in the ASM, but the increase in the proportion of sexually mature females simultaneously pregnant and lactating for the northern offshore stock and the decrease in the proportion of mature females in the population for the southern offshore stock over time were statistically significant. The mean estimate of ASM was significantly higher for the northern offshore stock, 11.1 years (SE=0.236), than for the southern offshore stock, 9.8 years (SE=0.264). No significant differences between stocks were found in the mean estimates of reproductive parameters. Our analyses of temporal trends in several biological parameters did not provide conclusive evidence for compensatory responses having occurred, and therefore some possible explanations are considered.

Manuscript accepted 17 June 1993.
Fishery Bulletin 91:611–618 (1993).

As population abundance declines, compensatory responses, such as increases in survival and pregnancy rates and a decrease in the average age at attainment of sexual maturity (ASM), are thought to occur (Eberhardt, 1977; Eberhardt and Siniff, 1977). Each situation must be carefully evaluated to determine whether compensatory responses will be detected because the magnitude of the parameter response and the range of population densities over which measurements are made are likely to be species specific, environmentally variable, and subject to parameter measurement error (Goodman, 1981; Fowler, 1981, 1988; DeMaster, 1984a; York, 1987). For species that are difficult to observe, unbiased estimates of survival rates are difficult to obtain, precluding their use as potential biological indices (Barlow and Boveng, 1991). Reproductive rates, however, are generally more easily measured and, if their relationship to population density is determined, may provide indices of compensatory responses for populations (Perrin and Donovan, 1984). For instance, Barlow (1985) reported that in the spotted dolphin (*Stenella attenuata*), the fraction of mature females pregnant, and the fraction of mature females simultaneously pregnant and lactating, may correlate well with per capita resource availability because these parameters were found to be relatively free of collection biases. The identification of biological indices (i.e., biological parameters that correlate with population abundance) would provide a useful management tool to distinguish between trends in population abundance resulting from exploitation or changes in environmental conditions (Hanks, 1981; Gerrodette and DeMaster, 1990).

The spotted dolphin is an ideal choice for this analysis because a lengthy time series of biological and population abundance data are available. This species is used as a cue by purse-seine vessel operators to find yellowfin tuna in the eastern tropical Pacific (ETP) (Perrin, 1969). Dolphins are incidentally killed during fishing operations, and the spotted dolphin population has had the largest number of animals killed in almost every year since 1959 (Smith, 1983; DeMaster et al., 1992). Two stocks of spotted dolphin, the northern offshore and southern offshore stocks, are recognized as separate management units in the ETP (Perrin et al., 1985). During the first decade of the purse-seine fishery, the 1960's, the large numbers of dolphins killed caused the abundance of these two stocks to decline. The northern offshore spotted dolphin was estimated to be between 35% and 50% of their pre-exploitation abundance (circa 1959) by 1979 (Smith, 1983), while the southern offshore stock was estimated to be at 92–98% of its pre-exploitation size (circa 1973) in 1979 (Smith[1]). Since 1976, both stocks of spotted dolphin are believed to have declined significantly in abundance (Anganuzzi et al., 1992).

As potential biological indices, we estimated ASM and associated reproductive parameters for two stocks of the spotted dolphin. Although for long-lived mammals, like the spotted dolphin, population growth rates are relatively insensitive to changes in ASM and reproductive rates (Eberhardt and Siniff, 1977; Fowler, 1981; Reilly and Barlow, 1986), these parameters have been correlated with changes in population abundance for other marine mammal species (Fowler, 1987). For instance, a decrease in ASM was correlated with a decline in population abundance for baleen whale stocks (Lockyer, 1984). Similarly, a decrease in ASM for crabeater seals was correlated with an increase in the per capita availability of food resources resulting from the exploitation and subsequent reduction in size of baleen whale stocks (Bengtson and Laws, 1985). Likewise, ASM for the striped dolphin of the western Pacific declined in response to exploitation and reduced population abundance (Kasuya, 1985). Based on the predictions of population responses to changes in density (i.e., increases in ASM and decreases in pregnancy rates as population abundance increases) presented by Eberhardt (1977) and Eberhardt and Siniff (1977), we predicted a decline in the ASM for both the northern offshore and southern offshore stocks of spotted dolphin after 1974 as well as a lower ASM for the more heavily exploited northern offshore stock. Similarly, a higher fraction of sexually mature females pregnant and those simultaneously pregnant and lactating should be observed for the northern offshore stock.

## Methods

Since 1968, when the National Marine Fisheries Service (NMFS) first placed observers aboard U.S. vessels to observe fishery activities, life history data has been collected from all cetacean species incidentally killed in the ETP yellowfin tuna purse-seine fishery. Beginning in 1974, life history data collection procedures were standardized, and the original sampling scheme that selectively collected large, female specimens was replaced by a random sampling scheme that selected the first available dead dolphins brought aboard (Perrin and Oliver, 1982). In 1979, the Inter-American Tropical Tuna Commission (IATTC) joined the NMFS in placing observers aboard U.S. vessels and collecting life history data.

The offshore stocks of spotted dolphin are distinguished geographically as being north or south of 1° south latitude (Perrin et al., 1985). The specimens used in our study were collected from these areas, but the sample of northern offshore stock animals was additionally restricted to those animals collected west of 120° west latitude (Fig. 1). The northern offshore stock was sub-sampled because exploitation has not been spatially uniform. The yellowfin tuna purse-seine fishery began primarily as a coastal fishery in 1959 and gradually expanded farther offshore. The Commission's Yellowfin tuna Regulatory Area (CYRA) was established in 1968 by the IATTC and provides a useful boundary that separates the inshore fishery area from the westernmost region of the ETP yellowfin tuna fishery (Peterson and Bayliff, 1985). The area west of the CYRA was not fished until the late 1960's, and then only for a few months a year. Exploitation in this region has been significantly less than inside the CYRA but much more than in the southern area which has been fished only sporadically since the early 1970's (Punsly, 1983). Although spotted dolphin move along the 10°N latitude as well as from the south to the west (Perrin et al., 1979a; Au and Perryman, 1985; Reilly, 1990), owing to the large size of the area, interchange between areas is probably limited. A standardized data collection scheme was established at about the same time as the fishery expanded into the western and southern regions of the ETP, and therefore we anticipated that these two distinct geographic regions would provide the best opportunity for testing potential biological indices.

Female spotted dolphins with complete life history data (i.e., geographic position, total body length, teeth collected, and both ovaries examined) collected between 1974 and 1988 were selected for this study. Few specimens have been collected from the southern offshore stock, and therefore all available specimens were prepared. Specimens from the northern offshore stock were selected randomly by year and the sample sizes distributed as evenly as possible between years so that annual estimates of ASM could be calculated. A maximum of 50 specimens per year was the target for selecting specimens from the northern offshore stock sample because Hohn (1989) showed that a sample size of 50 accurately estimated ASM and reduced the variance from an estimate based on a sample size of 25. Thin sections of the teeth were prepared and aged by one of us (ACM) with techniques described in Myrick et al. (1983). Prior to estimating age, all specimens were numerically coded in random order to disguise the specimen number so that no inference could be made about the stock or collection year for any speci-

The collection location and sample size of female spotted dolphin specimens selected for this study summarized by 2°-degree square block. The sample of northern offshore spotted dolphins was selected from north of 1° south and west of the Commission's Yellowfin tuna Regulatory Area (the dashed line), and the sample of southern offshore spotted dolphins was selected from south 1° south.

men. The associated life history data were also withheld until each specimen was aged.

ASM and its variance were calculated with the following formula (DeMaster, 1984b; Hohn, 1989).

$$\mathrm{ASM} = x + \sum_{i=x}^{j} p_i$$

$$s^2 = \sum_{i=x}^{j} \{[(p_i * (1-p_i)]/(n_i-1)\},$$

where, $x$ = age of the youngest mature animal,
$j$ = age class of the oldest immature animal,
$p_i$ = proportion immature in age class $i$,
$n_i$ = sample size for age class $i$.

Because population abundance estimates are not available for the geographic areas from which our samples were collected, we substituted year as a correlate for evaluating potential biological indices. We tested for temporal trends in ASM with a linear regression to determine whether the slope was statistically significantly different from zero. In addition, data for each stock were pooled for all years, and the null hypothesis of no difference between estimates of ASM for the two stocks was tested with a Student's *t*-test.

Other reproductive parameters examined include the fraction of the females mature, and the fraction of mature females that were either pregnant or lactating, or simultaneously pregnant and lactating. Trends in these parameters between 1974 and 1988 were tested by using a chi-square test for linear trends (Snedecor and Cochran, 1973), and the mean estimates for each parameter, all years combined, were tested for statistically significant differences with a chi-square test.

## Results

### Average age at attainment of sexual maturity

ASM was estimated for each year with sufficient data available (Table 1): 1976–1982 and 1984–1988 for the northern offshore stock sample, and 1976, 1979, and 1982 for the southern offshore stock sample. The regression line fit to the data for the northern offshore stock was not statistically significantly different from zero. We did not fit a regression line to the data from the southern offshore stock because only three annual estimates were available. The pooled estimate of ASM for each stock was 11.1 years (SE=0.236; $n$=520) for

**Table 1**

Number of samples by year and state of sexual maturity (immature or mature) for the northern offshore and southern offshore stocks of spotted dolphin used to estimate the average age at attainment of sexual maturity.

the northern offshore spotted dolphin and 9.8 years (SE=0.264; $n$=403) for the southern offshore spotted dolphin (Fig. 2). This difference in the ASM was statistically significant ($t$=14.32, df=13, $P<$ 0.001). The range in age of animals attaining sexual maturity was largest for the northern offshore stock. The youngest mature animal was 7 years, and the oldest immature was 16 years. The same range for the southern offshore stock was 6 to 11 years (Fig. 3).

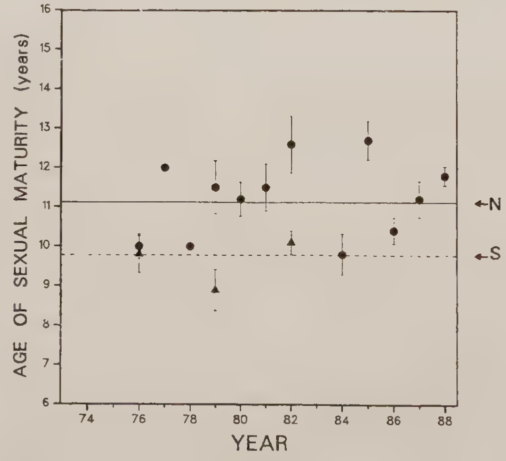

**Figure 2**

Estimates of the average age at attainment of sexual maturity (ASM) by stock for the offshore spotted dolphin with 1 SE. If no SE bar was plotted, then there were no overlapping indeterminate age classes. Circles represent estimates of ASM for the northern offshore stock and triangles are the estimates for the southern offshore stock. The pooled estimate of ASM for the northern offshore stock (N) is 11.1 years (solid line) and 9.8 years (dashed line) for the southern offshore stock (S).

## Reproductive rates

The statistically significant trends in the reproductive parameters examined were an increase in the proportion of mature females simultaneously pregnant and lactating in the northern offshore stock, the predicted compensatory response, and a decrease in the proportion of mature specimens in the sample from the southern offshore stock. When the data for all years were pooled, no statistically significant differences between the mean parameter estimates for the northern offshore and southern offshore stocks were detected (Table 2).

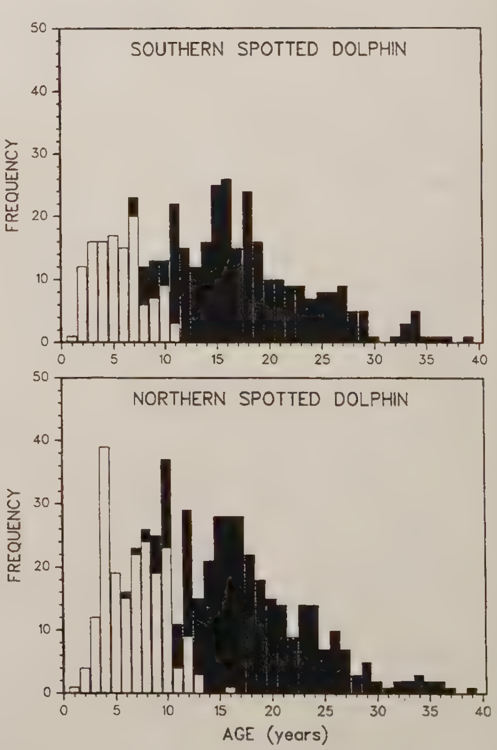

**Figure 3**

Age-frequency distribution of the northern offshore and southern offshore spotted dolphin specimens aged. The open bars represent the sexually immature females in the sample, and the solid bars represent the sexually mature females in the sample.

**Table 2**

The mean proportion of females by reproductive condition for the northern offshore and southern offshore stocks of spotted dolphin: the proportion of females in the sample that were sexually mature, and the proportion of sexually mature females that were pregnant or lactating, or simultaneously pregnant and lactating.

| Reproductive condition | Stock | |
|---|---|---|
| | northern | southern |
| Mature | 0.62 | 0.69 |
| Pregnant | 0.33 | 0.40 |
| Lactating | 0.55 | 0.47 |
| Pregnant and lactating | 0.06 | 0.06 |

## Discussion

Published evidence of density dependence in dolphin species is rare, and results are inconsistent. For example, in Japan, the striped dolphin, *Stenella coeruleoalba*, is heavily exploited, and the length of the lactation period is reported to have declined (Kasuya and Miyazaki[2]). For exploited spotted dolphins in the western Pacific, a decline in the ASM from 10.1 years in the 1961–63 cohorts to 8.6 years in the 1964–66 cohorts was reported, although the regression coefficient was not statistically significant (Kasuya, 1985). The decline in ASM for female striped dolphin from 9.7 years for the 1956–58 cohorts to 7.4 years in the 1968–70 cohorts was statistically significant (Kasuya, 1985). On the otherhand, for the spinner dolphin (*S. longirostris*) in the ETP, the less exploited southern whitebelly stock has a shorter lactation period than the more heavily exploited eastern spinner dolphin, the opposite of what would be expected for a compensatory response. The annual pregnancy rate, however, is lowest for the southern whitebelly stock and highest for the more heavily exploited eastern stock, as expected for density compensation (Perrin and Henderson, 1984). Barlow (1985) also reported differences in the proportion of mature female spotted dolphins (*S. attenuata*) that were pregnant between the eastern and western Pacific. The lowest proportion of mature females pregnant was observed in the more heavily exploited population, again, contrary to predictions based on the reported exploitation rates and estimates of population abundance for the ETP spotted dolphin. Also, for ETP spotted dolphins, the proportion of lactating mature females significantly increased from 46% in 1973 to 69% in 1981 ($P<0.05$) presumably in response to exploitation; no other statistically significant trends in reproductive parameters were found (Myrick et al., 1986).

Comparisons with other studies are difficult because in most cases the degree of exploitation relative to $K$ has not been quantified, and techniques to estimate age and ASM vary. In our study, statistically significant temporal trends were not detected for ASM but were detected for some of the reproductive parameters. The increase in the proportion of mature females simultaneously pregnant and lactating for the northern offshore stock and the decrease in the proportion of mature females in the population for the southern stock both suggest that the populations are growing. The fact that we did not observe the predicted compensatory responses in ASM may be due to one or more factors, including 1) too few data, 2) parameter estimation or measurement error, 3) a time lag in the response, or 4) biological differences between the stocks. Too few data and environmental periodicity (e.g., El Niño) may increase the variability in annual estimates of parameters, and both factors would reduce the ability to detect differences in potential compensatory responses (Goodman, 1984). The order in which parameters respond to changes in population density is not known, but time lags in responses may be expected owing to the late age at which these animals reach sexually maturity and the multi-year breeding cycle characteristic of the spotted dolphin (Goodman, 1981).

Data for the southern offshore stock of spotted dolphin, in particular, were limited and precluded testing for trends in ASM or the selected reproductive parameters. Although we selected our sample size, a maximum of 50 specimens per year for the northern offshore stock, on the basis of earlier work describing the effect of sample size on the variance for estimates of ASM (Hohn, 1989), our results indicate that larger sample sizes would be required to reduce the variance of the estimates in order to detect small, but biologically significant, changes (e.g., a 1.5-year difference) in ASM. Sample sizes of fewer than 50 per estimate of ASM resulted in too few specimens in the indeterminate age classes (i.e., those age classes with both sexually immature and mature animals) to estimate ASM accurately.

Another concern when analyzing data collected from a kill is whether the age distribution is representative of the population. All immature age classes appear to be underrepresented in both stocks, especially age classes between 10 and 15 years of the northern offshore stock (Fig. 3). This phenomenon was noted in a previous aging study of ETP spotted dolphin but occurred about five age classes earlier than the one we observed (Barlow and Hohn, 1984). This difference may be a result of different readers estimating age, although a Kolmogorov-Smirnov test to compare the age-frequency distributions of sexually immature and sexually mature animals from the two studies concluded that the samples were likely drawn from the same population. The underrepresentation of the immature age classes may be a result of segregation in the population by age and sex, fairly typical in large mammal populations, and may affect the estimation of ASM. We investigated the effect of this underrepresentation by assuming a stable age distribution and by apportioning the animals in the indeterminate age classes by sexual maturity under different assumptions of sexual maturity for animals in those age classes, and then calculated ASM. On the basis of segregation by age and sex observed in other species of large mammals, we predicted that the most reasonable scenario for reconstructing the age distribution is that the "missing" animals would be sexually immature. If this indeed were the case, we have underestimated ASM. Under this and other scenarios we investigated, estimates of ASM were consistently over- or under-estimated for both stocks. Therefore, possible sampling biases were unlikely to be responsible for the observed differences in ASM between the northern offshore and southern offshore stocks of spotted dolphin.

[2] Kasuya, T., and N. Miyazaki. 1975. The stock of *Stenella coeruleoalba* off the Pacific Coast of Japan. Pap. ACMRR/MM/SC-25 pres. at FAO Scientific Consultation of Marine Mammals, Bergen, February, 1976, 36 p.

The hypotheses we tested required that several implicit assumptions be made, including: 1) constant data collection biases, 2) minimal interchange of animals between areas, 3) consistent estimation of specimen age, 4) linear compensatory response with change in population abundance, 5) constant carrying capacity (*K*), and 6) equivalent initial life history parameters for the two stocks. The first three of the assumptions are believed to hold reasonably well. Barlow (1985) tested several of the same life history parameters we examined and found them to be relatively insensitive to a number of potential data collection biases; no major changes in the collection of life history data were made after 1974, thus supporting constant data collection bias as a reasonable assumption. Furthermore, the fishery operates in the same areas from year-to-year at approximately the same time of year. In fact, 60% of our sample from the northern offshore stock was collected between July and September, and a further 38% was collected between April and June; in the south, 57% of the sample was collected between January and March, and 27% was collected between October and December. This pattern of sample collection was consistent from year-to-year, and therefore would not affect the pooled or annual estimates of ASM or reproductive parameters. Geographic variability has been noted in earlier studies of spotted dolphin life history data (Hohn and Hammond, 1985; Barlow, 1985); thus selecting specimens from discrete areas as we did reduces the potential for geographic variability to obscure population compensatory responses. Similarly, estimating the age of all specimens at one time and in the blind ensured that age estimates were made as consistently as possible. Information about the validity of assumptions 4) and 5) is not currently available, but violations of the assumptions may provide explanations for our results. There is evidence for differences in the morphological and life history characteristics between the northern offshore and southern offshore stocks of spotted dolphin (see Perrin et al., 1976, 1979b, 1991[3]; Barlow, 1985; Hohn and Hammond, 1985; Myrick et al., 1986; Bright and Chivers[4]) that are likely correlated with the different oceanographic environments of the areas inhabited by these stocks (Au and Perryman, 1985; Reilly, 1990).

We did not find conclusive evidence for compensatory responses in these stocks of spotted dolphin as only one reproductive parameter for each stock showed a statistically significant trend. However, observed trends in both parameters suggest the populations are below *K* and declining. Our comparison of ASM's suggest further biological differences between the northern offshore and southern offshore stocks or populations. Currently, the order of compensatory responses and their dynamics are not known. In order to be useful as a biological index, a measure of the status of the population must be known and the dynamics of the parameter over a wide range of population densities quantified (Fowler and Siniff, 1992).

## Acknowledgments

We thank the NMFS and IATTC biological technicians who collected the life history data while aboard the tuna purse-seiners, often under difficult working conditions, and the Southwest Fisheries Science Center personnel that coded and edited the data for use. Priscilla Akin and Andrea Bright prepared the teeth for estimating the age of the specimens. We thank Jay Barlow, Douglas DeMaster, Andrew Dizon, Christina

# The Commercial, Subsistence, and Recreational Fisheries of American Samoa

PETER CRAIG, BONNIE PONWITH, FINI AITAOTO, and DAVID HAMM

Peter Craig, Bonnie Ponwith, and Fini Aitaoto are with the Department of Marine and Wildlife Resources, Box 3730, Pago Pago, American Samoa 96799. David Hamm is with the National Marine Fisheries Service, NOAA, 2570 Dole St., Honolulu, Hawaii 96822.

*ABSTRACT—Domestic fisheries in American Samoa landed 587,000 lb of fish and invertebrates in 1991 worth $993,000. Most of the catch (78%) and value (80%) was taken by the shoreline subsistence fishery that occurs on the coral reefs surrounding the islands. Artisanal fisheries for offshore pelagic fishes (primarily skipjack tuna,* Katsuwonus pelamis*; and yellowfin tuna,* Thunnus albacares*) and bottomfishes (snappers, emperors, groupers) accounted for 16% and 3%, respectively, of the domestic catch. Recreational tournament catches for pelagic fishes represented the remainder (3%).*

*While sport fishing is becoming increasingly important, other domestic fisheries have declined in recent years. The shoreline subsistence fishery has dropped by about 25% over the past decade owing to socioeconomic factors and possibly overexploitation. Artisanal fisheries have also declined precipitously in recent years owing to hurricane-related damages, attrition of fishermen, and competition with imports. Artisanal fisheries show some potential for growth, but may be constrained by marketing issues, vessel capabilities, and limited stock sizes (for bottomfish) or local availability of high-value (pelagic) fishes.*

*In contrast to the small-scale domestic fisheries, American Samoa is also homeport to a distant-water fleet of large purse seiners and longliners that fish beyond the EEZ and deliver about 160,000–220,000 short tons of tuna per year to local canneries.*

## Introduction

Many tropical islands in the South Pacific Ocean are confronted by rapidly growing human populations, but have few economic resources that their residents can utilize. Fish resources, from traditional subsistence fishing in times past to today's more modern boat-based fisheries, have always been an important component of island economies (Doulman and Kearney, 1991). It is therefore of interest to examine the current use and potential development of such fisheries. An overview of recent trends in the small, but locally important, domestic fisheries in American Samoa is presented in this paper. This includes four fisheries: 1) a shoreline subsistence fishery, 2) an artisanal fishery for offshore pelagic fishes, 3) an artisanal fishery for offshore bottomfish, and 4) a recreational tournament fishery. For completeness and contrast, the much larger distant-water fleet of commercial vessels that deliver tuna to canneries in American Samoa is also briefly described.

## Study Area

American Samoa, the only U.S. Territory in the southern hemisphere, consists of 7 small islands in the central South Pacific Ocean (Fig. 1). The largest islands are Tutuila and the Manu'a group (Ofu, Olesega, and Ta'u Islands). The total land area is only 77 mi.$^2$ . Most of the islands have steep volcanic slopes with limited flat land suitable for human habitation or agriculture. The Territory's population (46,600 in 1990), located primarily on Tutuila Island, is growing rapidly (3.7% per year) and has a doubling time of only 19 years (EDPO, 1991). The two major employers are the tuna canneries and the local government, which employ 33% and 31% of the labor force, respectively. There is a heavy reliance on imports for food, fuel, and materials (EDPO, 1991). Canned tuna is the only significant export, which supplies about 25% of all canned tuna consumed in the United States.

## Data Collection System

The Department of Marine and Wildlife Resources (DMWR) in American Samoa provides fisheries information to the National Marine Fisheries Service (NMFS) through its Western Pacific Fisheries Information Network (WPACFIN) and to the Western Pacific Regional Fishery Management Council (WPRFMC). The Council is responsible for managing fisheries within the 200–mile Exclusive Economic Zones (EEZ) around American Samoa, Hawaii, Guam, the Commonwealth of the Northern Marianas, and other U.S. possessions in the Pacific.

The historical development of DMWR has been described by Itano (1991). DMWR (initially the Office of Marine Resources) was established in the 1960's to oversee fisheries development projects and conduct resource assessments. In 1972, the development of artisanal fisheries began in earnest as did DMWR's data collection efforts. With assistance from WPACFIN in the 1980's, the data collection program was significantly upgraded and expanded to provide better coverage and statistics for all local boat-based fisheries.

General procedures for DMWR data collectors are to sample the artisanal fisheries two weekdays and one weekend (or holiday) per week, as described in detail by Aitaoto et al. (1991). During sample days, a creel survey is conducted as boats dock at designated harbors between 0500 and 2100 h. The fishermen are interviewed and their catches examined. To produce annual

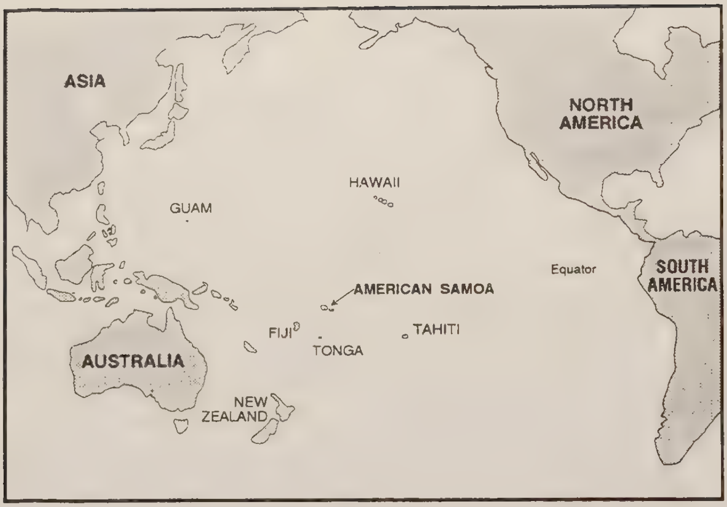

Figure 1.—Location of American Samoa (14° S, 170° W) in the South Pacific Ocean.

catch statistics, the creel survey information is computerized, verified, and expanded to account for times and areas not sampled. In the Manu'a Islands, the fishing fleet is small and the catch from nearly every boat is monitored; data are adjusted for the few trips not sampled. For recreational tournaments, DMWR provides the official weigh-in station and tallies landings from all participating boats.

The shoreline subsistence fishery on Tutuila Island was first examined in the late 1970's by Hill (1978) and Wass (1980). Beginning in 1991, the fishery is again being monitored by a creel and participation survey, conducted 3 days a week, stratified by time of day and type of day (weekday/weekend) (Ponwith, 1992). Catch data were first expanded to the entire study area along the south shore of Tutuila, where 35% of the people live. Then, on a per-capita basis, results were expanded to produce a Territorial catch.

The distant-water fleet that delivers tuna to canneries in American Samoa has been monitored by NMFS, either directly or by contract to DMWR, since 1963. The NMFS port sampling program collects vessel logbooks, length-frequencies of tuna species, and cannery summaries of vessel landings by species and gear type. Sampling procedures are described by Honda et al.[1] and Ito and Yamasaki[2].

## Regulations and Enforcement

Few of WPRFMC's regulations have focused on American Samoa's EEZ, because no major commercial fishery operates there at present. A goal, however, will be to insure that local residents have opportunities to participate in future fisheries developments that do occur. Preferential rights for indigenous people are currently being researched, and a control date (1 Jan. 1991) was set for possible implementation of a limited entry program for longline fishing. Occasional poaching by foreign vessels occurs in the EEZ, but no enforcement vessels or aircraft are available for surveillance.

Territorial regulations that apply to the management of local fisheries include record keeping for commercial fishermen, seafood dealers, and fish processors, as well as specific laws (mostly pertaining to reef users) regarding illegal fishing methods, gear restrictions, and species size limits. Enforcement of territorial regulations is at an early stage of development.

## Domestic Fisheries

The annual harvest of combined domestic fisheries in 1991 was 587,000 pounds, valued at $993,000 at local market prices. By far the majority of this catch (78%) and value (80%) was taken by the shoreline subsistence fishery (Fig. 2). It should be noted, however, that none of the domestic fisheries is strictly a commercial, subsistence, or recreational enterprise. These terms are used only to describe the principal nature of the fishery because some fish are sold and others are retained for personal use in each fishery. The percentage of fish sold varies consider-

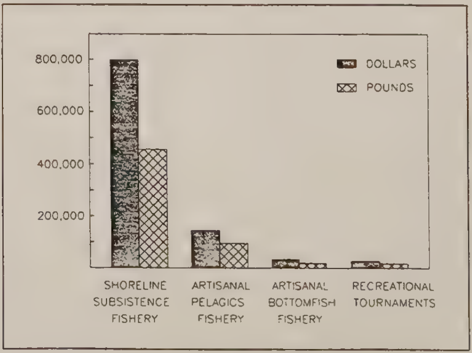

Figure 2.—Annual landings and value of four domestic fisheries in American Samoa in 1991. Units on the vertical axis refer to both dollars and pounds.

ably: Recreational tournaments (10% sold), shoreline subsistence fishery (25%), artisanal bottomfish fishery (65%), artisanal pelagic fishery (85%).

### Shoreline Subsistence Fishery

The islands of American Samoa are partially surrounded by a narrow fringing coral reef, the top of which is exposed at low tide. The reeftop and adjacent shallow waters are inhabited by a diverse array of fish and shellfish species (Wass, 1984; USACE[3, 4]) that are harvested by local residents on almost a daily basis throughout the year (Hill, 1978; Wass, 1980; Ponwith, 1992). Most fishing is accomplished by individuals on foot who fish in areas adjacent to their own village. Principal fishing methods used are rod and reel (which accounted for 37% of the annual catch in 1991), handline (25%), free diving (14%), gill netting (9%), gleaning (8%), and throw netting (5%). Gleaning involves the collection of fish and invertebrates at low tide, usually by hand, stick, or steel rod.

The 1991 island-wide subsistence catch on Tutuila Island was 439,000 pounds and was worth $768,000 at the average rate of $1.75/pound (Ponwith, 1992). Expanding these data to include limited catches in the Manu'a islands produces a total subsistence catch in the Territory of 456,000 lb, worth $798,000. The average catch per unit of effort (CPUE) was 3 pounds/gear-h; highest CPUE was obtained by gill netting (12.2 pounds/gear-h), followed by throw net (4.9 pounds/gear-h), free diving (2.9), rod and reel (2.9), gleaning (1.7), handline (1.4), and bamboo pole hook and line (0.7).

Virtually all fish and invertebrate species caught were retained for consumption or sale. Altogether, 69 species or species groups were harvested; fishes accounted for 86% of the total catch by weight. One coastal migratory fish species, the atule or bigeye scad, *Selar crumenophthalmus*, dominated the harvest in 1991 (Table 1). Jacks, surgeonfish, mullet, and octopus made up the majority of the reef-resident species taken. The average sizes of fishes taken were surprisingly small (Table 1), particularly for groupers and snappers which had very low mean weights (0.3–0.4 pound). Some favored species, such as giant clams, *Tridacna* spp., were generally absent in reef catches because of overharvesting.

Table 1.—Catch composition of the shoreline subsistence fishery on Tutuila Island in 1991.

| Reef species group | | Catch Composition (%) | Average Weight (lb) |
|---|---|---|---|
| Coastal Migrants | | | |
| Atule (big-eye scad) | *Selar crumenophthalmus* | 46 | 0.3 |
| Reef Residents | | | |
| Jacks | Carangidae | 10 | 1.4 |
| Surgeonfish | Acanthuridae | 9 | 0.5 |
| Mullet | Mugilidae | 6 | 0.9 |
| Octopus | *Octopus* sp. | 5 | 2.2 |
| Groupers | Serranidae | 3 | 0.4 |
| Sea urchins | Echinoid | 3 | |
| Palolo worms | *Eunice viridis* | 2 | |
| Squirrelfish | Holocentridae | 2 | |
| Snappers | *Lutjanus* spp. | 1 | 0.3 |
| Parrotfish | Scaridae | 1 | |
| Sea snails | Gastropoda | 1 | |
| Other | | 11 | |

Total catch: 439,000 pounds

One unique species taken was the palolo worm *Eunice viridis*, a burrowing polychaete. Palolo generally emerge once a year to release their reproductive segments (epitokes) into nearshore waters (Caspers, 1984; Itano and Buckley, 1988). Samoans, who consider the epitokes a delicacy, gather in large numbers (up to 1,000's) at midnight of the predicted night of emergence to collect the epitokes using scoop nets or long lengths of screen. Ponwith (1992) reported that palolo catches were highly variable (3,400 pounds in 1990, 600 pounds in 1991) because of the strength of the swarming event and the presence of offshore winds that concentrate the epitokes near the shoreline, making them more accessible to the villagers.

An opportunity to identify trends in the shoreline fishery was provided by two similar studies conducted in 1979 (Wass, 1980) and 1991 (Ponwith, 1992) on Tutuila Island. During this 12–year period, the island-wide catch decreased by 26%; however, differences in the run strength of the atule, an annually variable migrant to the shoreline area, tend to obscure an even greater decline in catch. In 1979 the atule catch was relatively small, only 13% of the total catch compared to 46% in 1991. By removing this species from the analyses and considering only the reef-resident species, a major drop is apparent in the adjusted island-wide catch (–54%) over the past 12 years, while effort decreased only 8% (Fig. 3).

Downward trends in catch and effort seem even more significant since there was a 46% increase in the human population during the same period (EDPO, 1991). With this influx of people and reduced fishing effort, the per capita subsistence catch on Tutuila Island dropped from 19.4 to 9.8 pounds. Some possible explanations for the reduced catch and effort include a decline in resource abundance (reflected by a drop in CPUE) or sociological changes such as less leisure time, a shift in dietary preferences, or a preference to buy fish at the market rather than to catch them personally. Imports of reef fish from Western Samoa and Tonga have occurred in recent years (at least 10,200 pounds in 1991) and appear to be increasing.

In general, the shoreline subsistence fishery appears to be declining, although it still far exceeds harvests of other domestic fisheries in American Samoa. Two notable exceptions to this apparent decline in interest are the directed fishing efforts for two highly prized species, the atule and palolo.

### Artisanal Fisheries

While local fishermen in American Samoa have harvested inshore fishes over the millennia, they have also made significant catches of offshore fishes since the 1970's. Itano (1991) describes in detail several "boom and bust" cycles that occurred over the years as various fisheries development projects were introduced. One of the more lasting projects was the small-boat "Dory Project" (1972–75) in which subsidized dory-type boats were made available to fishermen who then supplied catch information to DMWR. Though the project faded because of a variety of problems, Itano (1991) notes that it

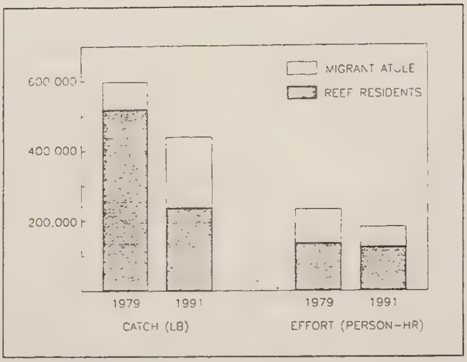

Figure 3.—Comparison of catch and effort in the shoreline subsistence fishery on Tutuila Island in 1979 (Wass, 1980) and 1991 (Ponwith, 1992).

inaugurated the current artisanal fisheries in American Samoa. Although catch statistics from the Dory Project are incomplete, CPUE data are available for comparison to current catch rates.

The two components of the current offshore artisanal fishery are 1) trolling for pelagic fishes in surface waters and 2) vertical handlines (with baited hooks) for bottomfish (Aitaoto et al., 1991). Fishing is typically conducted from small boats (e.g., 28-foot aluminum catamarans) fishing 1–25 miles offshore on 1-day trips. In 1991, boats participating in the pelagic fishery (30 boats) and bottomfish fishery (20 boats) landed relatively small amounts of fish, thus indicating the part-time nature of their participation in the fisheries. The average catch was about 130 pounds per trip in both fisheries, and the annual catch per vessel averaged 910 pounds of bottomfish and 3,030 pounds of pelagic fish.

### Artisanal Pelagic Fishery

Most pelagic fishing occurs in coastal waters, near seamounts, where seabird flocks are feeding (thus indicating the presence of baitfish that tuna may also be feeding upon), or at fish aggregation devices (FAD's) deployed around Tutuila Island. FAD's were introduced to American Samoan coastal waters in 1979 and have proven to be a popular way to increase the CPUE of widely dispersed pelagic fishes (Buckley et al., 1989). The lifespan of FAD's ranges about 3–30 months, and in recent years, 1–5 FAD's have been on station at any given time.

The artisanal catch of pelagic fish totaled 94,900 pounds in 1991, worth about $144,200 (this includes the value of pelagic fish retained for personal use) at an average price of $1.52/pound. Catches have ranged from 100,000 to 240,000 pounds in recent years (Fig. 4), and consisted primarily of skipjack and yellowfin tuna (Table 2). CPUE was variable (Fig. 5), as might be expected for oceanic migratory species, but current CPUE's are generally similar to CPUE's obtained during the start-up of the fishery in the 1970's (i.e., the Dory Project).

The recent drop in pelagic landings reflects, in part, recent hurricane-related damage (Hurricanes Tusi in 1987, Ofa in 1990, and Val in 1991), and the departure of several "highliners" from the fishery. Declines in revenue generated by the pelagic fishery (Fig. 6) from 1988 to 1990 were a result of drops in both landings and price; however, revenue made a slight comeback in 1991 owing to an increase in price. The pelagic fishery competes with an inexpensive and readily available supply of frozen fish that is purchased or bartered from foreign longline vessels delivering tuna to the canneries in American Samoa. In some cases, the domestic skippers themselves act as middlemen in such transactions. It is difficult to assess the influence that this fish source has on the market supplied by local fishermen, though Itano (1991) speculates that it inhibits the development of a viable artisanal fishery in the Territory.

**Table 2.—Catch composition of the artisanal pelagic fishery, 1989–91.**

| Pelagic species | | Catch in 1989–91 (%) Mean | Range |
|---|---|---|---|
| Skipjack tuna | *Katsuwonus pelamis* | 55 | 48–60 |
| Yellowfin tuna | *Thunnus albacares* | 28 | 26–32 |
| Blue marlin | *Makaira mazara* | 6 | 4–8 |
| Sharks | Miscellaneous | 3 | 2–4 |
| Dolphinfish | *Coryphaena hippurus* | 2 | 2–3 |
| Barracudas | *Sphyraena* spp. | 2 | 1–2 |
| Little tuna | *Euthynnus affinis* | 1 | 0–3 |
| Wahoo | *Acanthocybium solandri* | 1 | 1 |
| Dogtooth tuna | *Gymnosarda unicolor* | 1 | 1–2 |
| Other | | 1 | 0.2–1 |

Mean annual catch (lb): 124,200
Range (lb): 83,500–198,200

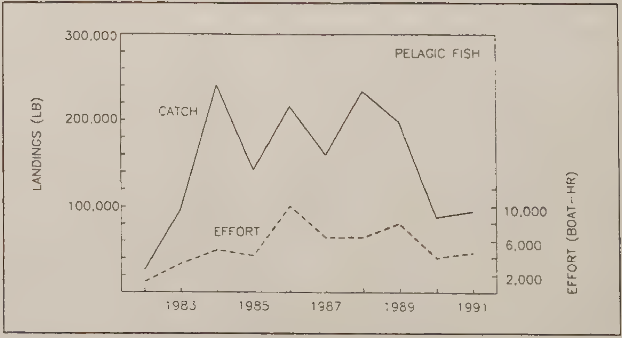

Figure 4.—Annual landings and effort of the artisanal fishery for offshore pelagic fishes.

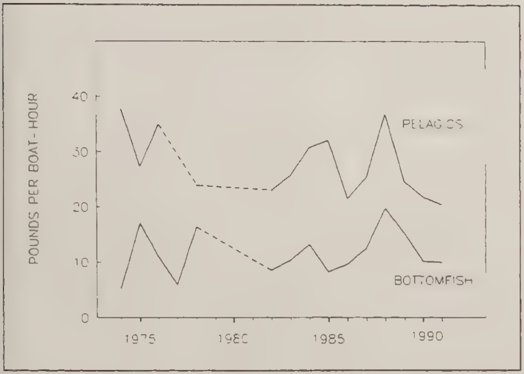

Figure 5.—CPUE trends for artisanal fisheries for bottomfish and troll-caught pelagic fishes. Data in 1977 were insufficient for pelagic catches, and no data were recorded in 1979–81.

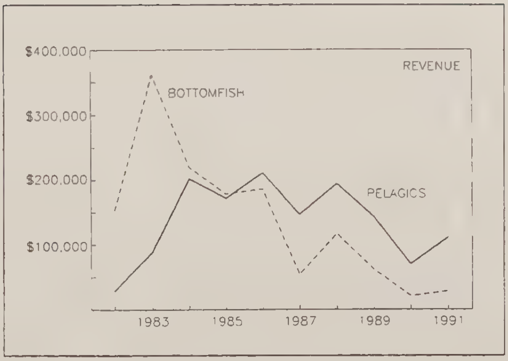

Figure 6.—Annual revenue (inflation adjusted) for artisanal fisheries for bottomfish and pelagic fishes. This graph illustrates commercial sales but does not include the value of fish retained for personal use.

## Artisanal Bottomfish Fishery

Bottomfish fishing occurs at depths of 15–100 fm around Tutuila Island and offshore seamounts. Suitable habitat for bottomfish is limited because the islands slope steeply into deep water and there are few seamounts in the Territory. The 100–fm isobath extends 110 n.mi. around the seven islands of American Samoa and 34 n.mi. around its seamounts (Itano, 1991). Dalzell and Preston (1992) estimate that the maximum sustainable yield (MSY) for deep slope bottomfish is about 8–27 t/year.

A small fishery for bottomfish was developed as a result of several government-funded projects in the 1970's and 1980's, and some high-valued fish (e.g., deepwater snappers) were shipped to Hawaiian markets for higher prices. But as these projects terminated and catches dropped, interest waned, and the fishery declined. The fishing grounds were "fished out" and catches probably exceeded MSY during this period (Itano, 1991).

In the past several years, the bottomfish fishery has collapsed to only 14% of its 1985 peak year (Fig. 7), and no fish are being marketed off the island. This decline appears to be due to several factors in addition to overfishing: Decreased subsidies to the fishery (Itano, 1991), the departure of several highliners from the fishery, and hurricane-related damage to local boats.

Snappers, emperors, and groupers accounted for most of the 18,100 pounds of bottomfish landed in 1991 (Table 3). This catch was worth $32,800 (this includes the value of bottomfish retained for personal use) at an average price of $1.81/pound. CPUE has varied between 10 and 20 pounds/boat-h, which is similar to CPUE's from the Dory Project in the 1970's (Fig. 5).

Revenue trends for the bottomfish fishery parallel the decline in catch (Fig. 6). Fishermen are also beginning to experience marketing conflicts with the recent influx of fresh bottomfish imported from Western Samoa and Tonga. In 1991 (the first year for which nearly complete data are available), imports of bottomfish were at least 19,400 pounds, thereby exceeding local landings of bottomfish.

## Tournament Fishery

Tournaments for pelagic fishes are popular events in the Territory. Typically, 7–14 local boats and 55–70 fishermen participate in each tournament, which are held 2–5 times per year, each lasting about 3 days. Tournament landings have been monitored almost yearly since 1974.

During 1974–92, the average fishing trip lasted 10 h and caught 12.3 pounds fish, for a daily trip average of 118 pounds (range 0–949 pounds), all species combined. After cancellation

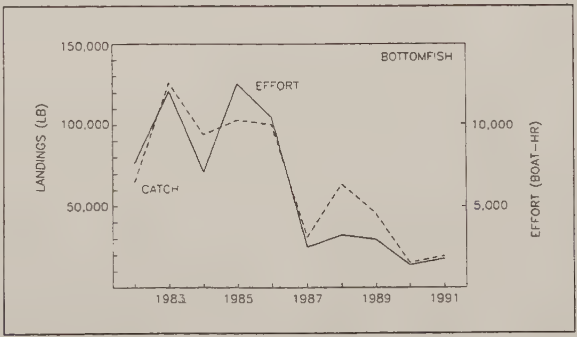

Figure 7.—Annual landings and effort of the artisanal fishery for bottomfish.

of most tournaments in 1990 in the aftermath of Hurricane Ofa, a sharp increase in participation and catches (as well as monitoring efforts) occurred in 1991 (Fig. 8). All reported landings (Fig. 8) are considered minimum estimates because 1) skipjack tuna and sharks were caught but often not reported because there was no tournament prize for them and 2) a fish caught might not be reported if a larger prize-winning one had already been landed.

The species composition of the five tournaments in 1991 consisted primarily of yellowfin tuna, blue marlin, and skipjack tuna (Table 4). Average and maximum weights of fishes caught (Table 4) are smaller than Hawaiian records, perhaps due to a much lower sport fishing effort in American Samoa.

**Table 3.—Catch composition of the artisanal bottomfish fishery, 1989–91.**

| Bottomfish species | | Catch in 1989–91 (%) Mean | Range |
|---|---|---|---|
| Bluelined snapper | *Lutjanus kasmira* | 17 | 14–20 |
| Redgill emperor | *Lethrinus rubrioperc.* | 12 | 11–14 |
| Gray jobfish | *Aprion virescens* | 10 | 7–14 |
| Longnose emperor | *Lethrinus elongatus* | 7 | 4–10 |
| Lunartail grouper | *Variola louti* | 6 | 5–8 |
| Other groupers | Serranidae | 6 | 2–10 |
| Humpback snapper | *Lutjanus gibbus* | 5 | 4–6 |
| Ambon emperor | *Lethrinus amboinensis* | 4 | 3–5 |
| Squirrel. snapper (ehu) | *Etelis carbunculus* | 4 | 3–6 |
| Jacks (unidentified) | *Carangidae* | 4 | 3–6 |
| Black jack | *Caranx lugubris* | 3 | 3–4 |
| Twinspot/red snapper | *Lutjanus bohar* | 3 | 2–4 |
| Longtail snapper (onaga) | *Etelis coruscans* | 3 | 2–4 |
| Other emperors | *Lethrinidae* | 3 | 2–4 |
| Peacock grouper | *Cephalopholis sonnerati* | 2 | 2–3 |
| Silverjaw jobfish (lehi) | *Aphareus rutilans* | 2 | 1–3 |
| Opakapaka | *Pristipomoides* spp. | 2 | 1–3 |
| Kusakar's snapper | *Paracaesio kusakarii* | 2 | 0–5 |
| Flower snapper (gindai) | *Pristipomoides zonatus* | 1 | 1–2 |
| Other | | 3 | 1–5 |

Mean annual catch (lb): 26,300
Range (lb): 15,400–45,300

**Table 4.—Catch composition and weight of fish caught in recreational fishing tournaments. Note that record weights for sharks and skipjack tuna may be artificially low because these were not target species.**

| Species | Composition in 1991 (%) | Tournament records[1] (lb) Mean | Maximum |
|---|---|---|---|
| Yellowfin tuna | 36 | 16 | 185 |
| Blue marlin | 23 | 132 | 542 (636)[3] |
| Skipjack tuna | 19[2] | 9 | 36 |
| Wahoo | 8 | 19 | 54 |
| Mahimahi | 6 | 23 | 51 |
| Sailfish | 4 | 75 | 110 |
| Shark | 1[2] | 87 | 125 |

[1] 1974–1992

[2] Minimum estimate due to incomplete reporting

[3] A nontournament blue marlin weighing 636 pounds was caught in 1984, and a larger one was caught but not recorded (H. Sesepasara, personal commun.).

The tournament CPUE for targeted species (blue marlin, yellowfin tuna, wahoo, and mahimahi) has been increasing over the years (Fig. 8), probably for several reasons. The fishermen are using better fishing gear and they have larger boats that can go farther offshore to fish around seamounts. In addition, the introduction of FAD's around Tutuila Island has resulted in higher catch rates (Buckley et al., 1989).

Tournament fishing is becoming increasingly important in American Samoa, and it contributed 3% of the total domestic landings in 1991 in only 16 days of fishing. The catch during this short period nearly equalled the yearly artisanal bottomfish harvest and amounted to 19% of the artisanal pelagic harvest.

## Commercial Tuna Fishery

In contrast to the small-scale nature of the domestic fisheries, American Samoa is also homeport to a distant-water fleet of large commercial vessels that deliver tuna to the canneries on Tutuila Island. These vessels fish beyond American Samoa's EEZ in the central and western Pacific Ocean. Fleet composition and landings have changed over the nearly 40 years that the canneries have been in operation, but it is beyond the scope of this paper to document these changes (see reports by Otsu and Sumida, 1968; Yoshida, 1975; Doulman, 1987; Schug and Galea'i, 1987; Honda et al.[1]; Ito and Yamasaki[2]).

The current fleet consists of 1) U.S. purse seiners that fish for skipjack and yellowfin tuna (about 30 vessels), 2) U.S. trollers that fish for albacore (about 30 vessels), and 3) foreign longliners that fish for albacore, yellowfin tuna, and bigeye tuna (about 70 vessels, mostly Taiwanese). In addition, transshipments of tuna are delivered to American Samoa by freezer vessels, and foreign sashimi longliners occasionally deliver part of their catch to the canneries.

Annual tuna landings in American Samoa have run about 160,000–220,000 short tons in recent years. Skipjack tuna accounted for most of the deliveries, followed by yellowfin tuna and albacore (Fig. 9). The catch by gear type was purse seine (50%), longline (14%), and troll (1%). The remainder (34%) was fish caught by purse seine and delivered to the canneries by freezer vessels.

## Discussion

Domestic fisheries may be small by commercial standards, but they are locally significant to the economy of American Samoa. The yearly harvest, originating primarily from the subsistence fishery on the coral reefs around

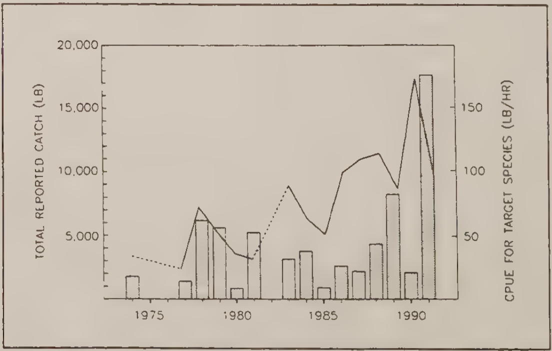

Figure 8.—Total reported catch of all species in fishing tournaments (bars) and CPUE (line) for the four principal target species: Blue marlin, yellowfin tuna, wahoo, and mahimahi. No data are available for 1975–76 and 1982.

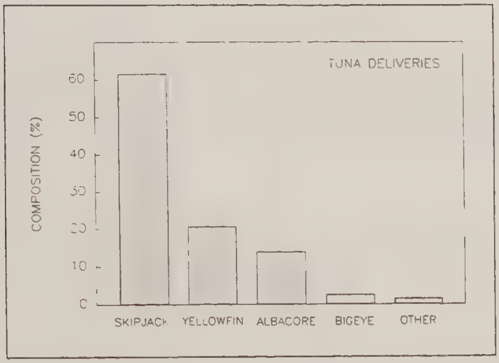

Figure 9.—Species composition of tuna delivered to canneries in American Samoa by the distant-water fleet of large commercial purse seiners and longliners.

the islands, amounted to 587,000 pounds worth nearly a million dollars in 1991. This dollar value does not fully represent the economic or social significance of this resource because of the subsistence component of Samoan culture and the generally low wage scale received by islanders who are employed.

A general decline in the catch and effort in the shoreline subsistence fishery has been noted, as might be expected in a society undergoing a shift from a subsistence economy to a cash economy. Nonetheless, the shoreline subsistence fishery still accounts for the major share of the total domestic catch and value. Consequently, there is a continuing need for the islands to better protect their reef resources from adverse impacts, some of which are readily apparent (e.g., pollution, siltation, destructive fishing practices). The scarcity of some highly sought reef species (e.g., giant clams), and the small sizes of fishes presently caught in the shoreline fishery also indicate that overfishing is probably occurring for some species.

Which of the domestic fisheries, if any, holds promise for further development? For the reasons outlined above, the shoreline subsistence fishery is an unlikely candidate. Similarly, the bottomfish fishery has already peaked because of the limited amount of suitable bottom habitat required by those species. However, considering the low level of fishing that occurs at present, the bottomfish fishery could withstand some increase in harvest.

Probably the least developed domestic fishery is that for pelagic fishes (tuna, marlin, swordfish, etc.) in the offshore waters of the Territory. These fishes are presumably part of large oceanic stocks which are unlikely to be diminished by small-scale artisanal fishing efforts. Rather, any expansion of this fishery will likely depend on several other factors. First, there are few local vessels at present that are large enough to undertake the multiple-day fishing trips necessary to fish profitably. None have freezer capabilities, and an adequate shoreside supply of ice is not yet available. Second, an increased supply of fish would quickly saturate local demands for fish, thus necessitating off-island marketing and shipping costs. Third, although pelagic resources are vast, their local availability may fluctuate because of seasonal variations or local depletions. Thus, a successful fishing enterprise by local residents would need to resolve important issues regarding vessel capabilities, marketing, and the availability of high-valued pelagic fishes in Territorial waters. However, an expansion of the sport fishery for pelagic fishes is not similarly encumbered, and indeed appears to be gaining popularity.

## Acknowledgments

The Department of Marine and Wildlife Resources appreciates the assistance provided by NMFS and WPACFIN in developing programs to monitor commercial fisheries within the Territory. The U.S. Fish and Wildlife Service provided funding through the Federal Aid in Sport Fish Restoration Act to examine noncommercial catches. We also thank Dave Itano and Dick Wass for their comments on this paper; Elliott Lutali for data processing; and Ioelu Seve, Alama Tua, Aitofele Sunia, Pita Ili, and Fa'apouli Niumata for data collection.

Honolulu Laboratory, 2570 Dole Street, Honolulu, Hawaii 96822

ABSTRACT: *Hapalotrema dorsopora* sp. n. from the heart of the green turtle *Chelonia mydas* is described. *Hapalotrema dorsopora* differs from all other members of the genus by having a separate dorsal uterine pore. *Hapalotrema dorsopora* most resembles *Hapalotrema mehrai* Rao, 1976, but differs, in addition to separate dorsal and ventral pores, in placement of testes and vitellaria and shape of ovary. *Hapalotrema postorchis* Rao, 1976, originally described from a single specimen, is redescribed.

KEY WORDS: Trematoda, *Hapalotrema dorsopora* sp. n., Spirorchidae, green turtle, *Chelonia mydas*, Hawaii.

From 1986 to 1988, 10 green sea turtles (*Chelonia mydas* L.) were found stranded on the islands of Lanai, Maui, and Oahu in Hawaii. The turtles were covered with neoplasms identified as fibropapillomas. Upon determination that the turtles would not survive, they were killed and examined for parasites. Eight turtles, 6 from Oahu, 1 from Lanai, and 1 from Maui, were found infected with an undescribed species of the genus *Hapalotrema* Looss, 1899.

## Materials and Methods

Worms were placed in tapwater and refrigerated overnight, fixed in alcohol–formalin–acetic acid for 2 days, and then transferred to 70% ethyl alcohol for storage. Whole mounts were stained in Semichon's acetocarmine, dehydrated in a graded alcohol series, and mounted in Canada balsam. Specimens for scanning electron microscopy were critical-point dried using $CO_2$ as the transition fluid in a Polaron critical-point dryer and mounted on specimen stubs using conductive graphite paint (TV tube coat). Specimens were coated for 10 min at 10 mA with gold-palladium in a Technics Hummer V sputter coater and examined with an AMR 1000 at 8–20 kV. All measurements are in micrometers unless otherwise indicated and are given as a range with the mean in parentheses. Illustrations were made with the aid of a drawing tube. Voucher specimens have been deposited in the USNM Helminthological Collection.

## Results

Seven species of digenetic trematodes were collected from 10 specimens of green turtles in Hawaii (Table 1). Trematodes of the genus *Hapalotrema* occurred as 35% of total worms recovered and in 80% of turtles examined.

## Description

### *Hapalotrema dorsopora* sp. n.
(Figs. 1–3, 7)

*Hapalotrema dorsopora* sp. n. Spirorchidae Stunkard, 1921. The following description based on 10 specimens.

SPECIFIC DIAGNOSIS: Body elongate, 9.2–10.6 mm (9.9) long, maximum width 0.59–1.1 mm (0.86) at midbody. Oral sucker terminal, 420–450 (430) long by 360–370 (368) wide. Esophagus tubular, 630–720 (680) long surrounded by large gland cells at bifurcation (at 8% of body length) anterior to acetabulum. Intestinal ceca slightly sinuous, terminating posteriorly near anterior end of Y-shaped excretory vesicle. Acetabulum larger than oral sucker, discoid, covered with minute spines, pedunculate, with folded outer margin, 583–684 (610) in diameter. Peduncle 526–631 (578) long by 390–430 (410) wide. Testes numerous, 78–177 (119) long by 52–112 (78) wide, separated into pre- (47–56) and postovarian (48–54) groups filling intercecal space. External seminal vesicle 262–396 (308) long by 90–195 (139) wide, intercecal, transverse between preovarian testes group and ovary. Cirrus sac 270–338 (297) long by 60–90 (73) wide with internal seminal vesicle, ejaculatory duct and cirrus. Male genital pore median, ventral, and sinistral to ovary. Ovary oval, submedian, with irregular margins, 577–763 (665) long by 579–736 (666) wide, between testicular groups. Seminal receptacle immediately posterior to ovary. Dorsal uterine pore, median, on raised muscular pad (Fig. 7), 21 posterior to vitelline

**Table 1. Digenetic trematode parasites found infecting 10 green turtles from Hawaii.**

| | Locality* | USNM Coll. No. | Prevalence | Mean intensity | Range |

* 1, Oahu; 2, Lanai; 3, Maui.

reservoir. Vitellaria mostly extracecal extending from pretesticular region to posterior extremity. Uterus short with metraterm, looping posteriorly from ovary to dorsal uterine pore. Eggs ($N = 10$) elongate with single or double polar filaments, 144–196 ([illegible]) long by 20–32 (26) wide.

HOST: Green turtle, *Chelonia mydas* L.

LOCATION: Heart.

LOCALITY: Kailua Bay, Oahu, Hawaii.

HOLOTYPE: USNM Helm. Coll. No. 82326.

PARATYPE: USNM Helm. Coll. No. 82327.

ETYMOLOGY: Dorso (L) = back; pora (L) = pore.

REMARKS: The new species most resembles *H. mehrai* Rao, 1976, but differs in size (*H. dorsopora* is larger); disposition of testes (first few preovarian testes only in 2 rows in *H. mehrai*, not found in *H. dorsopora*); placement of vitellaria (begin just posterior to acetabulum in *H. mehrai*, just anterior to testes in *H. dorsopora*); ovary entire in *H. mehrai*, irregular in *H. dorsopora*; dorsal uterine pore present in *H. dorsopora*, absent in *H. mehrai*.

### *Hapalotrema postorchis* Rao, 1976
### (Figs. 4–6)

Redescription based on 10 specimens. Body elongate, 10.3–12.8 mm (11.6) long, maximum width 1.0–1.8 mm (1.3). Tegument spinose; spines lost in frozen specimens. Oral sucker terminal, small, subspherical, 230–330 (250) wide by 240–360 (275) long; pharynx absent; esophagus narrow, thin-walled, 810–870 (832) long; bifurcating at 6–8% (7%) body length, just anterior to acetabulum, into 2 slender ceca, which extend to posterior extremities. Acetabulum slightly pedunculate, spherical, larger than oral sucker, 420–910 (714) in diameter, perimeter of sucker spinose, anterior edge at 9–12% (10.5%) body length. Testes few, 15–18 (17) measuring 430–620 (496) long by 280–420 (372) wide, separated by ovary into pre- (7–11) and postovarian (6–9) groups. Cirrus pouch large, 710–900 (840) long by 240–310 (285) wide, with internal seminal vesicle, ejaculatory duct and cirrus. External seminal vesicle transverse, between preovarian testes and ovary, measuring 480–670 (590) long by 250–380 (310) wide. Genital pore sinistral at lower level of ovary. Ovary lobed, between third and fourth quarter of body, 710–870 (775) long by 470–680 (618) wide. Vitellaria inter- and extracecal beginning 638–1020 (842), postacetabulum. Uterus short with metraterm. Eggs ($N = 10$) elongate with polar filament on each end measuring 140–330 (168) × 29–41 (32).

tion by Rao (1976), the measurements were taken from only 1 specimen. The specimen was not deposited in any collection and all attempts to examine the type material were unsuccessful. Differences seen between worms of this study and the Rao description are as follows. The acetabulum is slightly pedunculate and ringed with fine spines in the Hawaiian specimens. The total number of testes of the worm figured in the 1976 publication is shown at 19 (9 pre- and 10 postovarian). In our study, the maximum number found in any specimen examined was 18. The ceca are figured by Rao as bifurcating widely enough to circumvent the acetabulum. In the Hawaiian specimens, the ceca always continued behind the ventral sucker. Also, the vitellaria placement differs between the material in this study and those of the original description (beginning more posteriad in the Hawaiian material).

### Discussion

The blood flukes of sea turtles have been reviewed recently by Smith (1972) and Glazebrook et al. (1989). The genus *Hapalotrema* is separated from other members of the subfamily Hapalotrematinae Stunkard, 1921, by its large number of testes divided by the ovary and terminal genitalia into 2 groups (Yamaguti, 1958; Skrjabin, 1964). Smith (1972) lists 5 species of *Hapalotrema* in his review (*H. loossi* Price, 1934; *H. mistroides* (Monticelli, 1896) Stiles and Hassall, 1908; *H. orientalis* Takeuti, 1942; *H. polesianum* (Ejsmont, 1927) Byrd, 1939; *H. synorchis* Luhman, 1935). Glazebrook et al. (1989) list only 3 species of *Hapalotrema* in their table "Cardiovascular flukes recovered from sea turtles (1962 to present day)." There are currently 7 recognized species of *Hapalotrema* (Smith, 1972, omitted the 2 species from India, *H. mahrai* and *H. postorchis*, both described by Rao, 1976). All *Hapalotrema* species were described from marine turtles except *H. polesianum*. This species was originally found in the freshwater turtle *Emys orbicularis* and published as *Spirhapalum polesianum* by Ejsmont (1927) and later transferred to *Hapalotrema* by Byrd (1939). Only *H. mehrai* and *H. postorchis* have previously been recorded from *C. mydas*. *Hapalotrema loossi*, *H. synorchis*, and *H. mistroides* were all found in the loggerhead turtle (*Caretta caretta*) in Egypt, Florida, and an unknown locality, respectively. *Hapalotrema orientalis* was found in the hawksbill (*Eretmochelys squamosa*) on the island of Okinawa, Japan.

Two genera (*Hapalorhynchus* Stunkard, 1922, and *Coeuritrema* Mehra, 1933) from freshwater turtles have dorsal genital pores. However, the size of those pores is much smaller and less muscular than that described for *H. dorsopora*. This is the first report of a spirorchid trematode with separate dorsal (uterus) and ventral (cirrus) openings.

### Acknowledgments

The authors thank Ms. Carol Lyon and Dr. Tom Douglass of California State University, Long Beach, for their help with the figures. We also thank Dr. J. Ralph Lichtenfels of the U.S. National Parasite Collection for loan of specimens and Barry Choy, National Marine Fisheries Service, Honolulu Laboratory, for his help during the field portion of this study. This study was partially funded by NMFS Contract #40 JJNF 9-0091. We gratefully acknowledge this support.

## ABSTRACT

A large stone-like object was collected from the rectum of a leatherback turtle beached at Midway Atoll, Hawaiian Islands. It consisted of biomineralized faecal material, the mineral being struvite ($NH_4MgPO_4.6H_2O$). Much material of anthropogenic origin (plastics in sheet and linear form, plus other packaging materials and monofilament nylon) was incorporated into the faecolith structure. It is hypothesized that the formation of struvite stems from the interaction of the leatherback's osmotic physiology with the metabolism of faecal bacteria. While the formation of the faecolith may be pathological, it could alternatively be an adaptive response to package garbage (whether natural or man-made).

## INTRODUCTION

Beached adult specimens of the leatherback turtle *Dermochelys coriacea* Vandelli have almost invariably been drowned in nets, injured/killed by shark attack or in collision with boats. They may therefore be presumed to have been healthy beforehand. Necropsy sometimes reveals hard, round objects in the gut, particularly the hind gut. For example, the large male leatherback beached at Harlech in North Wales, UK (Eckert & Luginbuhl, 1988) had a hard, clay-like ball at the junction between the small and large intestines, while the rectum of a turtle beached at Midway Atoll in the northwestern Hawaiian Islands contained a hard, smooth, ovoid ball (the subject of this article). The aim of this investigation was to analyze the nature of this object, and perhaps elucidate the reasons for the occurrence of such faecoliths.

## MATERIALS AND METHODS

A large (13 cm in diameter), smooth, stone-like object was collected (on 1.4.91) from the rectum (at the junction with the cloaca, but displaced to one side of the gut in an outpouching of the rectum) of a freshly-stranded specimen of *Dermochelys coriacea* at Midway Atoll at the northwestern end of the Hawaiian archipelago (28° 13' N, 177° 21' W) (see Fig. 1) . Leatherbacks are known to forage in the pelagic habitat to the north of Midway Atoll where they are not uncommonly entangled in Japanese, Taiwanese and Korean driftnets (Balazs, 1982). However, this was the first leatherback ever known to strand at Midway. The turtle had clearly been the victim of a shark attack as it had been decapitated very recently and lost all four flippers. Fresh blood was still flowing from its wounds and several sharks were swimming in shallow water immediately off the beach where the turtle stranded. On dissection (which revealed perfectly fresh tissues) the object was found immediately, so cannot have been an artifact of post-mortem deterioration.

The object was divided into two portions, one being sent to the UK for detailed analysis, while the other was used only for gross investigation. The faecolith portion sent to Britain was held for a few days in a water-saturated atmosphere. This caused the structure to soften. It was broken up and studied beneath a binocular microscope. During these observations, numerous small, hard, transparent crystals were seen embedded in the brown material of the softened faecolith structure. The crystals were dense and insoluble in water; they were separated from the rest of the material by washing and stirring. Crystals were prepared for X-ray probe microanalysis by freeze drying and attachment to an aluminium stub with double-sided adhesive tape. Crystals were studied in a scanning electron microscope (SEM) fitted with an energy dispersive X-ray microanalyser. A total of 10 faecolith crystals were investigated.

Once the elemental composition had been established, further crystals were investigated by X-ray diffraction. 20-30 of the larger and cleaner crystals were hand-picked under a binocular microscope and ground in an agate pestle and mortar under deionized water. The resultant slurry was spotted onto a glass slide and allowed to dry at room temperature. During drying the slurry was mixed using a scalpel blade in an attempt to minimize any preferred orientation. A diffractometer trace was obtained from this slide using CuK$\alpha$2 radiation in a Philips diffractometer.

## RESULTS

### GENERAL DESCRIPTION OF FAECOLITH

At the macroscopic level it was found that the smooth, rounded faecolith contained much material of anthropogenic origin (see Table 1). The rest of the faecolith appeared to be of an amorphous brown nature, with a strong faecal odour.

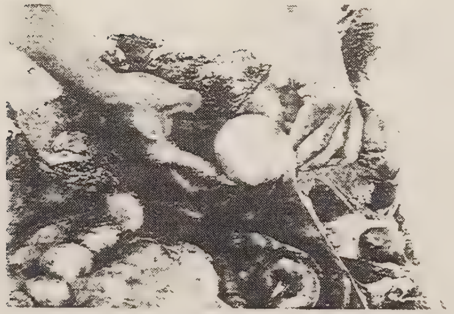

Fig. 1. Photograph of stranded leatherback, showing faecolith in situ.

At the microscopic level it could be seen that the brown material was made up of lamellae of soft material, which presumably consisted mainly of faecal bacteria (large numbers of bacteria were visible in early 'dirty' SEM preparations of the faecolith crystals). Between each of the lamellae were huge numbers of crystals (ca. 0.2-0.3 mm length, flattened and coffin-shaped). The crystals were transparent, colourless, hard, brittle and apparently insoluble in water.

## FAECOLITH CRYSTAL COMPOSITION

First, it was noticed that the crystals prepared for X-ray microanalysis by freeze-drying appeared white and chalky rather than transparent; this indicated that the original crystals contained water of crystallization. All ten faecolith crystals subjected to X-ray microanalysis showed very similar patterns to that shown in Fig. 2. There are three obvious peaks. The Al comes from the stub on which the crystal is mounted; the Mg and P are the major elements of the crystal itself. Particularly surprising is the low amount of Ca; the faecolith was clearly not calcified.

X-ray microanalysis is largely qualitative, and calculation of peak areas yields only semi-quantitative information (see Morgan, 1985 for discussion). However, calculation yielded the following mean compositions (SD in parentheses): Na 1.6 (0.5)%, Mg 32.2 (1.9)%, Si 0.9 (0.3)%, P 67.1 (2.3)%, Cl 0.7 (0.8)%, K 0.3 (0.5)%, Ca 2.2 (1.5)%. From these values it may be seen that virtually all of the identified elemental material present in the crystals consists of Mg and P, with some crystal surfaces (particularly clean ones with no contaminating material visible on the surface) approaching levels of 100%. The technique is not capable of detecting the presence of elements with an atomic number below 11 (e.g. C, H, I or O), so although the X-ray microanalysis results, combined with the observation of crystalline rather than amorphous structure, strongly suggest that the crystals are almost pure magnesium phosphate, the technique cannot discriminate between different types of phosphates (e.g. between various orthophosphates, some of which contain H, and pyrophosphate), and cannot eliminate the possibility of the presence of ammonium in the crystals (as in struvite, $NH_4MgPO_4.6H_20$).

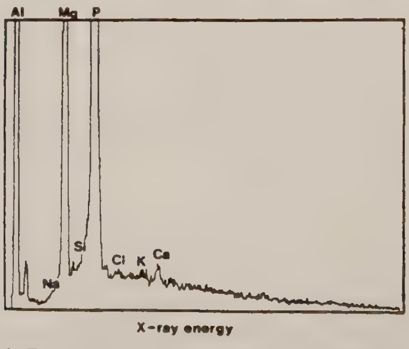

Fig. 2. Trace derived from X-ray dispersive microanalysis of faecolith crystals. Al is from the stub on which the crystal was mounted.

1. 300 mm length of tangled, blue polypropylene twine (5 mm thick).
2. 4 strands (120 mm, 105 mm, 120 mm, 130 mm) of old, unravelled polypropylene tarpaulin fabric, all 1 mm wide.
3. 160 mm length of monofilament nylon fishing line (approx. 8 lb breaking strain).
4. 4 pieces of green, hard, flat plastic (9x13 mm, 10x7 mm, 6x5 mm, 6x5 mm).
5. Piece of flat, white hard plastic (9x5 mm; 2 mm thick).
6. Piece of flat, yellow-orange hard plastic (5x5 mm).
7. 3 small strands of plastic (20 mm, 20 mm and 30 mm in length).
8. 6 small pieces (approx. 4 mm diameter) of expanded polystyrene foam.
9. Piece of unknown hard substance (6x5 mm).
10. Numerous polystyrene beads (< 1 mm diameter).
11. 3 pieces (each approx. 20 mm diameter) abraded material from polythene bags

TABLE 1. Material of anthropogenic origin incorporated in faecolith

The magnesium phosphates are all insoluble or only very slightly soluble in water, so degree of solubility cannot separate the forms, but the X-ray diffraction pattern gave a near-perfect match for struvite (JCPDS pattern number 15-762). The morphology of crystals is very similar to that recorded by LeGeros & LeGeros (1984) from struvites synthesized in gel systems. A good general description of struvite (also known as guanite) may be found in Palache *et al.* (1951).

## DISCUSSION

Faecoliths are present in some stranded leatherbacks, but certainly not all; Den Hartog & Van Nierop (1984) did not report any in the six *Dermochelys* they studied. At present it is difficult to decide whether their presence indicates a pathological condition, or is a normal feature of turtle biology. Except for the injuries caused by the shark attack, the Midway turtle showed no obvious signs of disease and there was no compaction of plastic in the gut. The adaptive formation of hard nodules in the gut of marine animals is not unknown; the heart urchin *Echinocardium* ingests fragments of wood or stone which act as a substratum for the formation of bacterial nodules which fix and detoxify sulphur as insoluble metal sulphides. There is also a general tendency in marine invertebrates for detoxification by binding metals in insoluble, granular form. It is feasible that the formation of a smooth, rounded object around non-biodegradable garbage may facilitate later defaecation. Leatherbacks not only swallow plastic bags and man-made garbage such as the twine and polystyrene reported here; they are also known to swallow wood, feathers, sand and seaweed (e.g. Brongersma, 1969; Den Hartog & Van Nierop, 1984)). It would appear that they will swallow almost any material swimming or floating at the sea surface; some of this material was presumably difficult to pass through the gut even before man started to throw non-biodegradable garbage into the sea. However, there is an extensive veterinary literature concerned with the consequences for captive animals of swallowing of foreign bodies (see Frye, 1991 for reptilian examples), but except in the case of crocodilian gastroliths (swallowed deliberately for control of buoyancy and/or digestive efficiency) the responses of animals seem to be pathological rather than adaptive. The occurrence of hard masses in the intestine of chelonians is not uncommon either (see Frank, 1981), but these are usually formed from masses of chitinous parts of insects or accumulated indigestible cellulose fibres. Such masses can cause constipation, though intestinal parasitic nematodes may help to break the masses down.

From the form of the leatherback faecolith studied here it is clear that its hardness stems from biomineralization, presumably by the gut bacteria rather than the leatherback itself, since the mineral crystals are deposited between the bacterial lamellae. It is most interesting that the mineral is non-calcareous and composed of struvite which may be formed in the laboratory by mixing magnesium sulphate solution with an acid solution of ammonium phosphate (Palache *et al.*, 1951). Struvite is not a common biomineral in a global sense, although it is well recognized in medical and veterinary circles. The principal occurrence in live organisms seems to be as a component of urinary stones in mammals (including cats and humans) resulting from alkalinization due to bacterial infection (e.g. Prien & Frundel, 1947; LeGeros & LeGeros, 1984; Lowenstam & Veiner 1989). Geological struvite occurrences have unusual bulk compositions and are non-marine (e.g. within fossil cave guano deposits); struvite has also been found in dung-peat mixtures and in canned food (Palache *et al.*, 1951). In these occurrences too, bacterial activity is probably significant.

In view of the association with bacterial lamellae in the faecolith, a similar origin seems likely in this case. A further factor may be enrichment of the hindgut fluids of the leatherback turtle by divalent ions. *Dermochelys* has to drink seawater like any other marine reptile (or teleost fish). It can only absorb water by pumping Na across the gut wall until sufficient osmotic gradient exists for water to flow osmotically from gut lumen to blood. In consequence, the hind gut fluid is likely to contain relatively high concentrations of magnesium, calcium and sulphate ions, but little sodium or chloride. However, the ammonium and phosphate ions of struvite are presumably derived from the faecal bacteria. LeGeros & LeGeros (1984) report that struvite can be formed in a calcium-rich medium at pH values between 7 and 9, and that formation of small crystals is actually promoted by high calcium concentrations, so it is not necessary to postulate a calcium-poor or acid environment in the hindgut.

## ACKNOWLEDGEMENTS

The authors are grateful to Prof. K. Simkiss and Dr. G. Durant for advice, to R. Miya for technical assistance, and to M. Sigman for assistance with dissection.

# Modeling the potential of fishery reserves for managing Pacific coral reef fishes

**Edward E. DeMartini**
Honolulu Laboratory, Southwest Fisheries Science Center
National Marine Fisheries Service, NOAA
2570 Dole Street, Honolulu, Hawaii 96822-2396

**Abstract.**–The potential use of marine fishery reserves (MFRs) for managing fisheries on tropical Pacific coral reefs was assessed with an extension of the Beverton-Holt model. The effects of year-round fishery closures on harvests in adjacent, exploited areas were evaluated. Potential changes in spawning stock biomass per recruit ($SSB/R$) and yield per recruit ($Y/R$), when varying fractions of exploitable reef area were closed to fishing, were estimated from published data, approximated natural and fishing mortality rates, size- and maturity-at-age distributions, and "transfer" (emigration and immigration) rates. For select cases, fundamental transfer rates were adjusted for possible density-dependent emigration from closed areas as relative densities decreased in surrounding non-closed areas because of continued fishing. Three hypothetical "fish types" were constructed, bracketing the likely extremes in fundamental transfer rates and related life-history parameters of Pacific coral reef fishes: a small-bodied, fast-growing and short-lived, strongly philopatric species of damselfish was contrasted with a large-bodied, relatively slow-growing, long-lived, vagile species of jack. A "surgeonfish" type was used to represent intermediate parameter values.

Simulations corroborate previous observations that MFRs contribute little, if anything, towards increasing Y/R. Results for the highly vagile jack confirm that rapid transfer rates will negate potential gains in $SSB/R$ resulting from closures. At the opposite extreme, small reef philopatriots like damselfishes would almost never be harvested, because of negligible transfer rates, unless the MFR was periodically opened to fishing. The simulations suggest that the $SSB/R$ of the surgeonfish type is the most likely to benefit from MFRs, because moderate vagility allows biomass to accumulate within the closure despite harvesting in the non-closed area. Results further suggest that growth rate, fishing effort in the non-closed (open) area, natural mortality, and maturity and harvesting schedules importantly influence the potential of MFRs to augment SSB when transfer rates are low to moderate.

Manuscript accepted 5 March 1993
Fishery Bulletin 91:414–427 (1993).

Marine fishery reserves (MFRs), areas closed to harvesting and adjacent to fished areas, have recently been touted as enforceable and cost-effective alternatives to conventional fisheries management measures such as size and bag limits, closed seasons, and limited entry (Davis, 1989; Plan Development Team 1990; Polacheck, 1990; Bohnsack, in press; Davis et al.[1]; Russ et al., in press). MFRs are recognized worldwide as providing sanctuaries in which local populations of desirable species can increase in abundance or attain larger body sizes (McCormick and Choat, 1987; Alcala, 1988; Buxton and Smale, 1989; Clark et al., 1989; Russ 1985, 1989; Alcala and Russ, 1990; Cole et al., 1990; Bennett and Attwood, 1991). In contrast, harvesting is known to alter the abundance and body size distributions (Craik, 1981; Katnik, 1982; Koslow et al., 1988; Plan Development Team 1990) and assemblage structure (Bell, 1983; Russ and Alcala, 1989) of fishes on coral reefs and other localized regions of fishery exploitation.

By providing havens from exploitation within which organisms can attain large adult body sizes, designated refuges protect the most valuable segments of spawning stocks (Plan Development Team, 1990). For most marine organisms with lengthy (≥2 wk-long) planktonic larval stages, MFRs can function as sources of benthic recruits to exploited, often distant, sink populations. The subsequent contribution of these recruits to the fishery might counteract (or forestall) the effects of recruitment overfishing (Carr and Reed, in press; Russ et al., in press). Through the directed movements of settled stages, MFRs might also augment the standing biomass of stocks, including spawning adults, in exploited areas adjacent to MFRs as well as within the MFRs themselves (Polacheck, 1990; Roberts and Polunin, 1991). MFRs thus might provide a management tool that addresses growth overfishing, particularly for multispecies fisheries on tropical coral reefs where conventional management is ineffective (Roberts and Polunin, 1991).

Despite the recognized importance of MFRs as sanctuaries for conserving biomass, their contribution to fishery stocks and yields in adjacent exploited areas is poorly understood (Davis, 1989; Polacheck, 1990; Roberts and Polunin, 1991; Russ et al., in press). An introduction to the problem is provided by Polacheck (1990), who expands the Beverton-Holt equation (Beverton and Holt, 1957) describing the effects of a year-round refuge on the spawning stock biomass ($SSB$) and yield of a cohort in a surrounding exploited area. Although areal closures on coral reefs are one identified application, Polacheck's (1990, Table 1) simulations use empirical data on the growth, maturity, and harvesting schedules of Georges Bank cod *Gadus morhua* and haddock *Melanogrammus aeglefinus*. The growth and mortality dynamics of tropical coral reef fishes, however, may be quite unlike those of higher-latitude species (Munro and Williams, 1985; Longhurst and Pauly, 1987). Further simulations using growth and mortality data of other fishes are needed.

---

[1] Davis, G. E., S. C. Jameson, and J. E. Dugan. Potential benefits of harvest refugia in Channel Islands National Park and Channel Islands Marine Sanctuary. Unpubl. manuscr., 25 p. U.S. Natl. Park Service, Channel Islands National Park, CA 93001.

Observations of traditional practices by marine islanders (Johannes, 1978) suggest that reserves can augment the *SSB*, and perhaps the yield of tropical reef fishes. To date, controlled empirical measurements of fishery yields in an area adjacent to a MFR have been published for only one study site (Sumilon Island, central Philippines; Alcala and Russ, 1990). The changes in catches that Alcala and Russ (1990) observed, however, were based on yield, not yield per recruit ($Y/R$), over a 1-year period and therefore may not have represented equilibrium conditions.

The present paper evaluates the effects of permanently closed MFRs of different sizes on net changes in *SSB* and yield for several types of tropical Pacific reef fishes. The author simulated various combinations of fishing mortality and emigration-immigration ("transfer") rates for fishes having different but typical natural growth and mortality schedules. Because tropical reef fishes have higher natural growth and death rates than do temperate zone fishes, the focus is on the relative sensitivity of spawning stock biomass per recruit ($SSB/R$) and $Y/R$ to MFR size, transfer rates, variations in natural mortality and growth, fishing effort, and age at first capture. Another objective is to compare the management potential of "single large or several small" (SLOSS) (Simberloff, 1988) reserves of equal total area. Finally, the potential of MFRs on island reefs is discussed, with particular reference to reef areas surrounding the island of Oahu, Hawaii.

## Methods

Parameter values for von Bertalanffy growth rates, derived mortality rates, and maturity and harvesting schedules were chosen to bracket the spectrum of life histories and exploitation characteristics of tropical Pacific reef fishes. At one extreme, values were assembled to describe a reef transient (e.g., a jack of the family Carangidae) that is relatively slow-growing but long-lived and large-bodied is likely to travel rapidly over relatively large distances. Such species often support valuable commercial fisheries. Values used for growth and mortality rates of the jack resemble those of many species of commercially important snappers, groupers, and jacks from the South Pacific and other tropical seas (Munro, 1983; Munro and Williams, 1985).

A short-lived, fast-growing but small-bodied reef damselfish (family Pomacentridae), with limited movements after settlement, was used to represent the opposite extreme. Such small tropical reef species are collected for the aquarium fish trade.

In between these two extremes lies a broad continuum of fishes with intermediate longevities, body sizes, and movement rates. These fishes probably represent most species targeted by recreational and artisanal fisheries on tropical reefs. The few data available (Galzin, 1987; Ralston and Williams[2]; Russ and St. John, 1988; Dalzell, 1989) suggested a range of moderate growth and mortality rates for a number of Pacific parrotfishes (family Scaridae) and surgeonfishes (family Acanthuridae). For convenience, these fishes were labeled the "surgeonfish" type.

The growth parameters used in this study were based partly on published values for a particular species population, complemented by data for other Pacific populations of the same species. For the pomacentrid, the author used a Moorean population of *Stegastes nigricans* (Galzin, 1987). He selected *Ctenochaetus striatus* as the surgeonfish; the length-weight relation was based on a Moorean population (Galzin, 1987), and a Samoan population provided the VBGF parameters (Ralston and Williams, 1988). Sudekum et al.'s (1991) data for NWHI *Caranx ignobilis* were used to represent the jack. Thus the degree to which values were population-specific varied among the three fish types. Natural mortality rates ($M$) were estimated using Pauly's (1980) multiple regression of $M$ on maximum size, growth coefficient, and mean water temperature (Pauly and Ingles, 1981); 25°C was chosen as representative for shallow, tropical Pacific waters. All parameter values used are listed by fish type in Tables 1 and 2.

### Modeling closure effects

Polacheck's (1990) model of the effects of closure size (1–50%), rates of fish transfer between closed and exploited areas, and fishing mortality rate on the biomass and production of fishes in an adjacent exploited area was used with one small but important difference: the use of a three- rather than a four-sided closed area. (Closures on island reefs usually extend seaward from the shoreline, so fishes can move across upcoast, downcoast, and offshore boundaries only. Other factors being equal, dispersion rates out of and into shore-

### Table 2

Age-specific parameters used to simulate the standing stock and catch (yield) values for each of the reef fish types described in Table 1.

| Fish type | Age (yr) | Mean weight[1] (g) | Percent mature[2] | Partial recruitment[3] |
|---|---|---|---|---|
| Damselfish | 1.0 | 4.77 | 100 | 1.00 |
| | 2.0 | 32.40 | 100 | 1.00 |
| | 3.0 | 72.20 | 100 | 1.00 |
| Surgeonfish | 1.0 | 40.81 | 0 | 0 |
| | 2.0 | 101.87 | 100 | 1.00 |
| | 3.0 | 164.43 | 100 | 1.00 |
| | 4.0 | 217.18 | 100 | 1.00 |
| | 5.0 | 257.24 | 100 | 1.00 |
| Jack | 1.0 | 110.0 | 0 | 0 |
| | 2.0 | 861.7 | 0 | 0 |
| | 3.0 | 2587.0 | 0 | 0 |
| | 4.0 | 5348.6 | 100 | 1.00 |
| | 5.0 | 9061.8 | 100 | 1.00 |
| | 6.0 | 13,569.6 | 100 | 1.00 |
| | 7.0 | 18,688.4 | 100 | 1.00 |
| | 8.0 | 24,235.1 | 100 | 1.00 |
| | 9.0 | 30,042.0 | 100 | 1.00 |
| | 10.0 | 35,963.5 | 100 | 1.00 |
| | 11.0 | 41,878.8 | 100 | 1.00 |
| | 12.0 | 47,691.4 | 100 | 1.00 |
| | 13.0 | 53,327.1 | 100 | 1.00 |
| | 14.0 | 58,731.1 | 100 | 1.00 |
| | 15.0 | 63,865.3 | 100 | 1.00 |

[1] Based on mean weight-at-age estimated from weight-specific VBGF; see Table 1 for sources.

[2] Sexual maturity assumed 100% complete at age corresponding to the asymptote of the Von Bertalanffy growth function curve; all fish were assumed immature prior to this age.

[3] All species were defined as fully recruited to the fishery at the age of 100% sexual maturity, no fish entering the fishery prior to that age: Age-at-first-capture, $A_c$ = 1.0, 2.0, and 4.0 years for the damselfish, surgeonfish, and jack, respectively.

line-bounded reef closures will be one-fourth slower than the respective rates for completely nested closures of equal areal extent.)

Polacheck's modified Equation 8 was

$$T_{12} = 3 \cdot T_{1s} \cdot (R_1 / R_s)^{-1/2}; \qquad (1)$$

where $T_{12}$ is the instantaneous emigration rate from closed area 1 to exploited area 2; $T_{1s}$ is the emigration rate from a closure of $R_s$ standard size; and $R_1$ is the fractional closure size evaluated. As in Polacheck (1990), the initial fish densities were assumed homogeneous in both areas, and thus the number of fish initially present in area 1 at time $t$ was defined as

$$N_{1,t} = R_1 \cdot N_{total,t} \qquad (2)$$

where $N_{total,t}$ = number of individuals in the cohort entering areas 1 and 2 at time $t$. $T_{1s}$ was allowed to vary among fish types, as types surely differ in their fundamental emigration and immigration rates. Selected values of $T_{1s}$ spanned realistic values for each fish type (damselfish: 0.001, 0.01, and 0.1; surgeonfish: 0.1, 0.25, and 0.5; jack: 0.1, 0.5, and 1.0). $T_{21}$, the rate of immigration into area 1 from area 2, given the type-specific value of $T_{1s}$, was as defined by Polacheck (1990, Equation 6).

A basic assumption of the model is that fishing does not affect fish distributions by altering habitat or by promoting density gradients between areas 1 and 2, i.e., dispersal is random and uniform throughout both areas and across their boundaries (Polacheck, 1990). This is realistic for fishes like jacks that range widely or that have very large home ranges. However, the assumption of uniform dispersal throughout both areas is debatable for fishes with home ranges that are small relative to the size of MFRs, particularly for strongly site-attached, territorial species like damselfishes whose ambits are trivial compared to the area of a reserve. Transfer rates that functionally approximate those based on an assumption of uniform, random dispersal might be tenable for home-ranging (or even territorial) organisms, if emigration out of MFRs into adjacent fished areas followed a "stepping stone" pattern with minimal time lags. Limited field data at present both support (Walsh, 1984) and counter (Wellington and Victor, 1988) such a model. The key factors here are the magnitude of time lags and the relative sizes of individual home ranges within particular MFRs.

An $R_s$ value of 0.10 was used to represent the "standard-size" closure (Polacheck, 1990). Fishing mortality rates ($F_c$) were input over the range from 0.1 to $\geq 3M$, with special evaluation of $F_c = 0.5M$, $M$, and $2M$, based on the best estimate of natural mortality for each fish type. Total fishing effort ($F_2$) was homogeneously redistributed throughout the exploited area and fixed in magnitude (at a given $F_c$), regardless of the size of the closed area (Equation 7 in Polacheck, 1990).

*SSB*/*R* and *Y*/*R* are used as the primary bases of evaluation. Although measures of biomass are not usually applicable to species like the damselfish that are harvested on a numerical basis (see Ingles and Pauly [1984] for examples of consumptive exploitation of small-bodied fishes in artisanal fisheries), these measures were evaluated in the same way to maintain consistency.

First, the *SSB* and yield of a cohort were calculated, by using Polacheck's (1990) Equations 2 and 3 for the numerical standing stock and the numerical catch of each cohort comprising that stock:

$$\sum_{(t=1)}^{n} (N_{1,t+1} \cdot \bar{W}_{t+1} \cdot \%\mathrm{mat}_{t+1}), \tag{3}$$

$$\sum_{(t=1)}^{n} (N_{2,t+1} \cdot \bar{W}_{t+1} \cdot \%\mathrm{mat}_{t+1}), \text{ and} \tag{4}$$

$$\sum_{(t=1)}^{n} (C_{2,t} \cdot \bar{W}_t); \tag{5}$$

where $N_{1,t+1}$ and $N_{2,t+1}$ are the numbers of a cohort surviving in the respective area at time $(t+1)$; $C_{2,t}$ is the numerical catch of a cohort in area 2 at time $t$; $\bar{W}_t$ and $\bar{W}_{t+1}$ represent the mean weights of individual fish of the cohort at times $t$ and $(t+1)$, respectively; and $\%\mathrm{mat}_{t+1}$ is the percentage of the cohort that is sexually mature at time $(t+1)$.

*SSB*/*R* and *Y*/*R* were then calculated by standardizing the total spawning biomass and yield, respectively, of the cohort over its life span by the total number of recruits potentially (area 1) and directly (area 2) entering the fishery from that cohort (Gabriel et al., 1989). *SSB*/*R* was evaluated in terms of percentage of the virgin stock biomass possible if fishing was disallowed in both areas (Polacheck, 1990); 20% of virgin biomass was considered the threshold for recruitment overfishing (Beddington and Cooke, 1983).

Two series of simulations were run. One series treated the $T_{12}$ and $T_{21}$ values as fixed, assuming that, analogous to Polacheck's (1990) analyses for Georges Bank cod, transfer rates would remain constant and independent of relative fish densities in the two areas. Additional simulations, using the same initial $T_{1s}$ values, were run for selected cases; in these runs, subsequent values of the transfer rates were treated as a density-dependent function of the changing, relative fish densities in the two areas. Subsequent values of $T_{12}$ and $T_{21}$ were adjusted as follows:

$$T_{12,t+1} = T_{12,t} \cdot \{ (N_{1,t}/N_1) / (N_{2,t}/N_2) \}^x, \text{ and} \tag{6}$$

$$T_{21,t+1} = T_{21,t} \cdot \{ (N_{2,t}/N_2) / (N_{1,t}/N_1) \}^x; \tag{7}$$

where $N_1$ is defined in Equation 2 and $N_2$ is the initial number of the cohort present in area 2; $N_{1,t}$ and $N_{2,t}$ are the numbers of fish surviving in the respective area at subsequent age $t$; and $x$ is the power used to scale the ratio of fish densities. In Equations 6 and 7, the ratio of the numbers of fish surviving at time $t$ was further adjusted by the ratio of initial densities in the two areas in order to scale for the propensity to emigrate at the onset. Two values of $x$ were evaluated: 0.125 (eighth root) and 0.5 (square root). (Note: When $x$ equals 0, the $T_{12}$ and $T_{21}$ are fixed; when $x$ equals 1.0, these rates are continually readjusted by the changing ratio of relative densities.) Exponents of 0.125 and 0.5 were chosen because they bracketed rate changes of reasonable magnitude. In the surgeonfish, for example, an eighth-root adjustment would initially accelerate a median $T_{1s}$ of 0.25 by about 20% for a median closure size of 25%, at an $F_c$ of 1.0. The corresponding rate increase due to a square-root adjustment would be 60%.

Inclusion of a term for the density-dependent adjustment of transfer rates, as stocks are fished-down in the non-closed area, extends Polacheck's (1990) evaluation. This is perhaps an unnecessary refinement for stocks such as Georges Bank cod for which harvesting by trawl might reduce habitat quality in the non-closed area (Polacheck, 1990). However, non-destructive (e.g., hook and line) methods of artisanal fisheries on coral reefs do not reduce habitat quality. Furthermore, fishes may emigrate at an accelerated rate from a closure into the surrounding non-closed area where densities continue to decrease (tantamount to improving habitat quality). Compensatory emigration resulting from a density gradient is recognized as potentially important in the siting and design of nature reserves (Schonewald-Cox and Bayless, 1986).

## Complementary simulations

In addition, the effects of varying $M$ and the age-at-first capture ($A_c$) on total biomass per recruit ($B/R$) were simulated with the conventional $Y/R$ model of Beverton-Holt (Sparre et al., 1989). Fishing mortality was evaluated at $0.5M$, $M$, and $1.5M$ or $2M$. $A_c$ was examined with the most reasonable estimate of $A_c \pm 50\%$ for each of the three fish types (see footnote C of Table 2 for the type-specific values of $A_c$ used in modeling closure effects). An age-at-recruitment to fishery habitat ($A_r$) value of 1.0 year was assumed for the surgeonfish and jack, and an $A_r$ of 0.5 year for the damselfish.

## Results

### General

Results corroborate several of Polacheck's (1990) major results: *SSB/R* increased, while *Y/R* generally decreased, with increasing refuge size (Fig. 1). Even in cases where a closure positively affected yield, *Y/R* increased little. *Y/R* often was greater at higher levels of fishing effort (Fig. 1) and usually decreased at larger refuge sizes; the rate of decrease was less at higher fundamental transfer rates (Fig. 2, A–C). *SSB/R* was generally greater for closures of larger size at any particular transfer rate (Figs. 1 and 2). The positive effects of a closure of a given size on *SSB/R* were greater at lower rates of exploitation and diminished at higher transfer rates (Fig. 3). The rate of increase in *SSB/R* with refuge size was greater at lower transfer rates (Fig. 1, A–C). The progressive gain in *SSB/R* usually was greater than the progressive loss in *Y/R* for refuges of increasing size (Fig. 2).

Another general pattern was the relative importance of the interactive effect of natural and fishing mortality rates, compared to age at recruitment to the fishery. For most combinations of $M$ and $F_c$, *B/R* was more strongly influenced by these two rates than by age at recruitment (Fig. 4, Table 3). Depending on fish type, *B/R* values ranged two- to five-fold as $M$ and $F_c$ values varied ±50% of their midpoint estimates, but ranged only twofold or less as $A_c$ varied ±50% (Table 3).

By comparison, transfer rates had relatively little effect on *SSB/R*, compared with the effects of natural and fishing mortality rates. For a median-sized closure of 25%, changes in percentage of virgin *SSB/R* differed <10% within fish type for transfer rates that varied as much as two orders of magnitude (Fig. 3).

Another generality, not previously made explicit, is that ages at maturity and at first capture can more strongly influence spawning stock than can the presence and size of a refuge. The presence of a refuge will have a relatively weak effect on spawning biomass if the resource begins to be heavily exploited well before sexual maturity. In extreme cases, *SSB/R* might not be appreciably enhanced by large closures, despite relatively low transfer rates.

### Fish types

Perhaps the most significant, specific result of the simulations was that fish types differed in how refuge size affected *SSB/R* levels. Large, apparent gains in percent virgin *SSB/R* of the damselfish occurred only at the expense of large losses in yield (Figs. 1A, 2A, 3A). Nontrivial (>5%) gains in percentage *SSB/R* of surgeonfish could occur at small (0.1) refuge sizes, although the overall rate of increase in *SSB/R* would be greater for larger closures (Figs. 1B, 3B). For the jack, however, gains in *SSB/R* of magnitude similar to those of the surgeonfish could be realized with increasing refuge size only for large ($R_1 > 0.3$) closures (Figs. 1C, 3C).

Simulation results appeared to vary among fish types in response to their differing growth rates and natural mortality and exploitation schedules. For example, in comparing the results for the high-mortality surgeonfish with those for the low-mortality jack, substantive gains in *SSB/R* of the jack (restricted to large closures) were further restricted to low ($F_c \le 0.4$) levels of fishing effort (Fig. 1C). *SSB/R* dropped below 20% of the virgin stock at $F_c = 0.3$, the fishing effort that was optimal for maximizing *Y/R* (Fig. 1C). For the surgeonfish, appreciable (≥10%) gains in *SSB/R* could occur under heavy ($F_c > 1$) exploitation rates for refuges as small as 10–20% (Fig. 3B), and ≥20% of virgin *SSB/R* can be sustained at $F_c \le 1.15$ (Fig. 1B).

The observed differences among fish types in the potential for MFRs to increase *SSB/R* also were strongly influenced by the ages at sexual maturity and recruitment to the fishery. Ages at first maturity and at first capture were attributes that differed greatly among the three fish types (damselfish: age 1; surgeonfish: age 2; jack: age 4; Table 2). Median *B/R* (equal to *SSB/R* for all except the damselfish at $A_c$ = 0.5 year) varied by 30% for the damselfish, 100% for surgeonfish, and 35% for the jack among ages at first capture that varied ±50% of their respective midpoints (Table 3). Compared with age at first catch, transfer rates had less effect; *SSB/R* consistently varied ≤10% for the damselfish (with twofold variation in very low transfer rates; Fig. 3A), for the surgeonfish (with fivefold variation in moderate transfer rates; Fig. 3B), and for the jack (with tenfold variation in rapid transfer rates; Fig. 3C). At a reference $F_c$ of 1.0 and a median closure size of 25%, *SSB/R* varied from <6 to 35% of virgin stock biomass, depending on fish type (Fig. 1, A–C).

### Compensatory transfer rates

Even small (eighth root of density ratio) compensatory increases in transfer rates could have negated potential increases in *SSB/R* that might result from the presence of a closure. A larger adjustment with the square root of the density ratio, of course, can have an

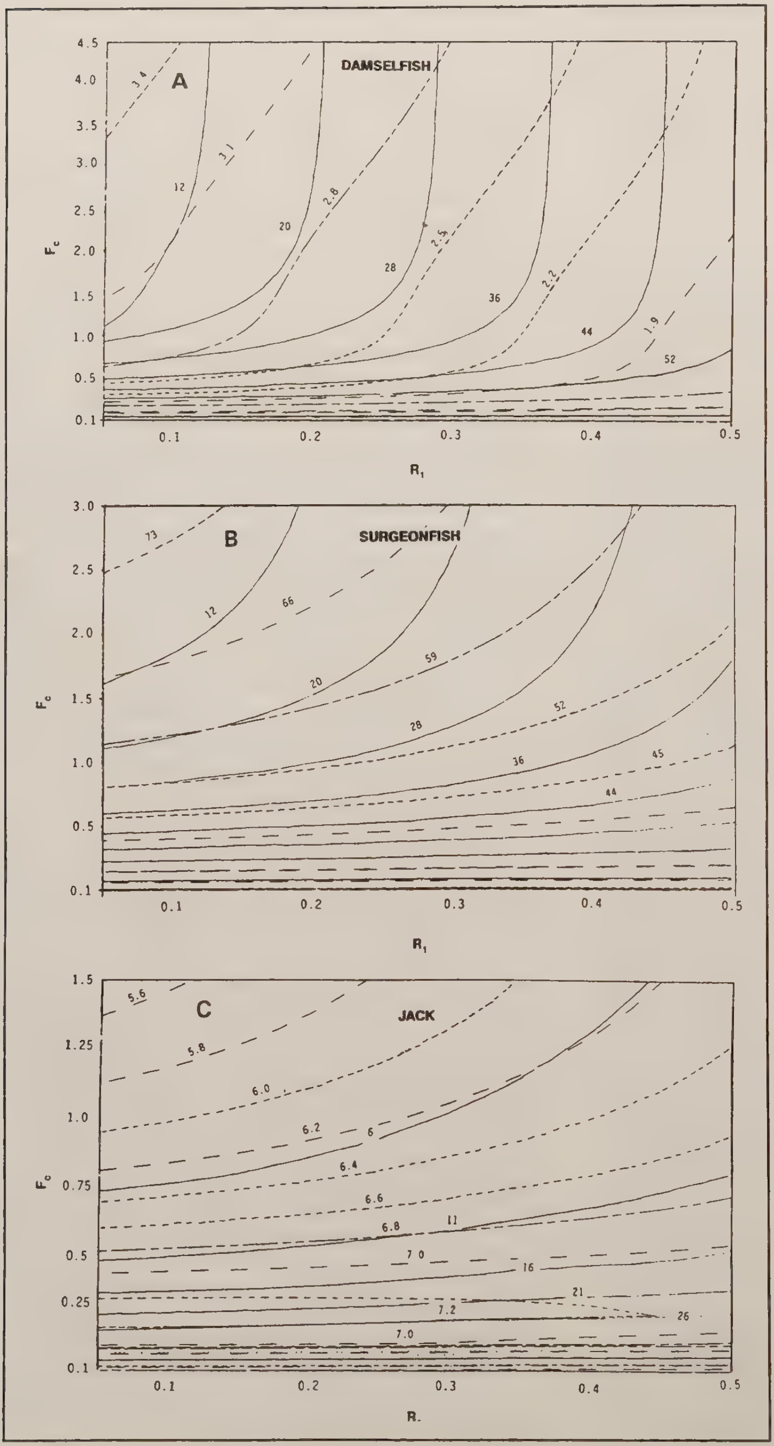

**Figure 1**

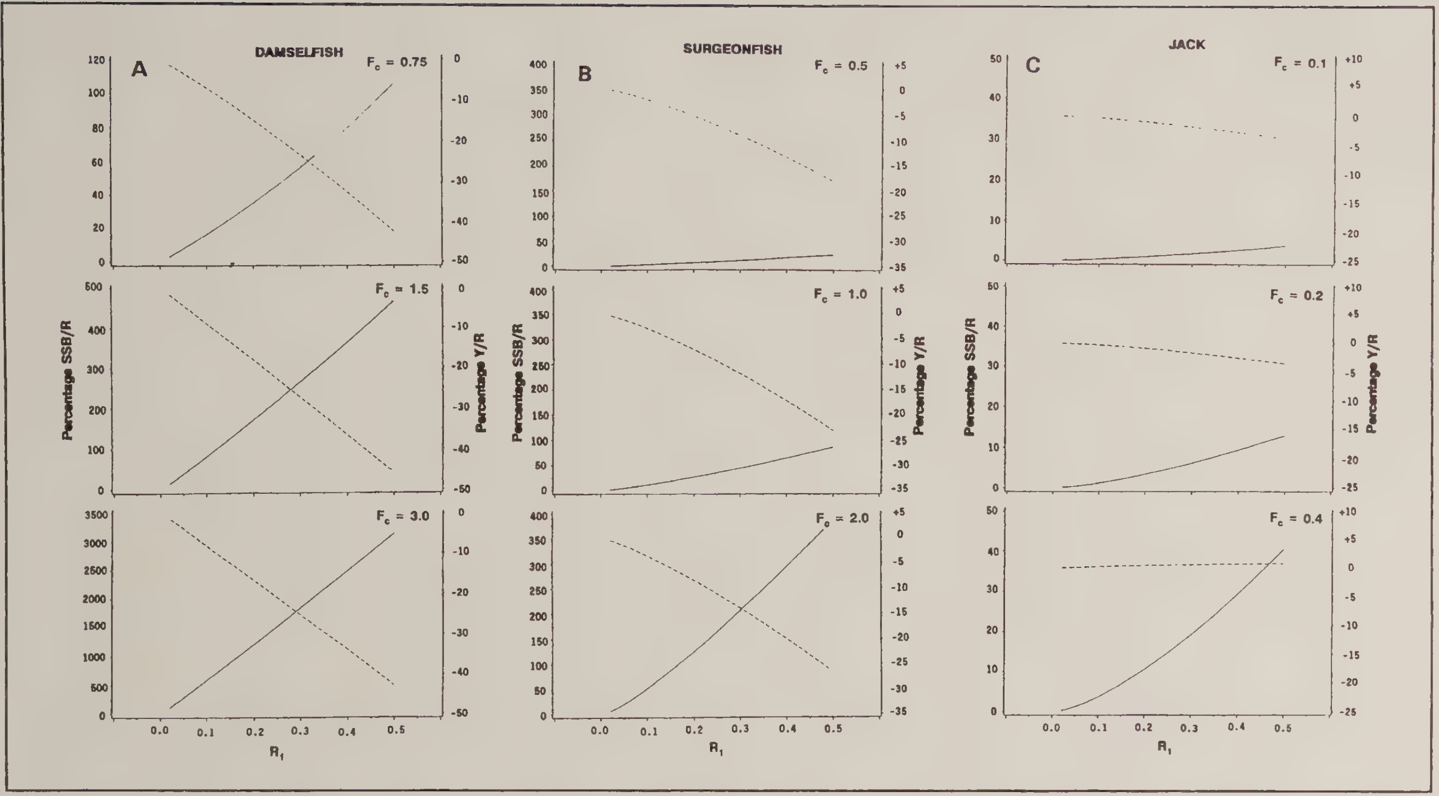
Overlay of a yield-per-recruit surface (various dashed lines) on a percentage spawning stock biomass-per-recruit surface (solid lines) as a function of refuge size ($R_l$) and fishing mortality rate ($F_c$) when transfer rate ($T_{1s}$) is constant: (**A**) damselfish ($T_{1s}$ = 0.01); (**B**) surgeonfish ($T_{1s}$ = 0.25); and (**C**) the jack ($T_{1s}$ = 0.5). Spawning biomass values are expressed as a percentage of virgin biomass that would accrue if no fishing were allowed in areas 1 and 2.



## Figure 2

Percentage changes in spawning stock biomass per recruit (*SSB/R*; solid line) and yield per recruit (*Y/R*; dashed line) as a function of refuge size ($R_1$), when transfer rate ($T_{1s}$) is constant, for different fishing mortality rates ($F_c$): **(A)** damselfish ($T_{1s}$ = 0.01); **(B)** surgeonfish ($T_{1s}$ = 0.25), and **(C)** the jack ($T_{1s}$ = 0.5). Spawning biomass and yield values are standardized by the biomass and yield that would accrue if there were no closure (i.e., both areas 1 and 2 open).

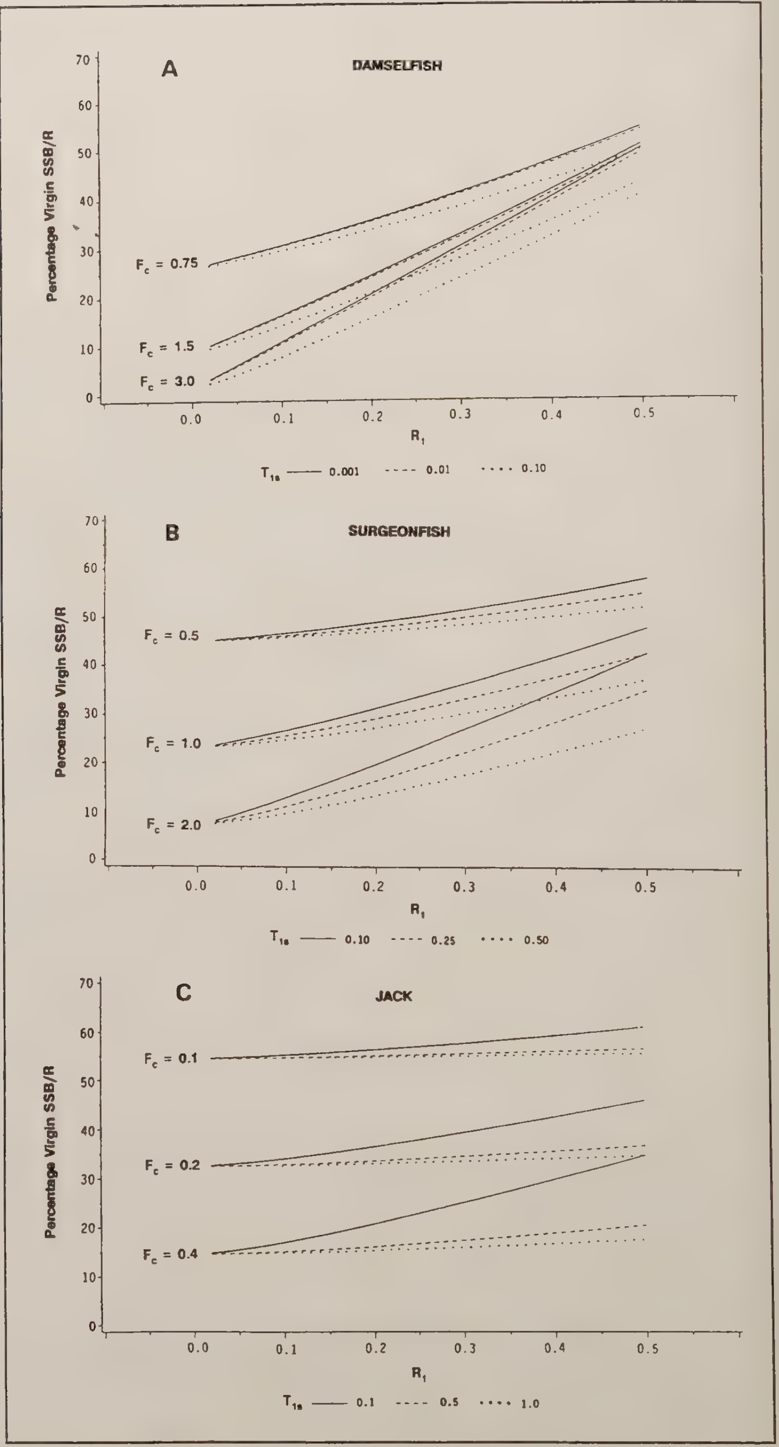


**Figure 3**

Relative changes in spawning stock biomass per recruit ($SSB/R$) as a function of refuge size ($R_1$) compared at fishing mortality rates ($F_c$) equal to natural mortality rates ($M$) of $0.5M$, $M$, and $2M$, among a range of possible fundamental transfer rates ($T_{1s}$) for (**A**) damselfish (in grams), (**B**) surgeonfish (in grams), and (**C**) the jack (in kilograms). $SSB/R$ values are standardized by the respective virgin biomass value that would accrue if no fishing were allowed in areas 1 and 2.

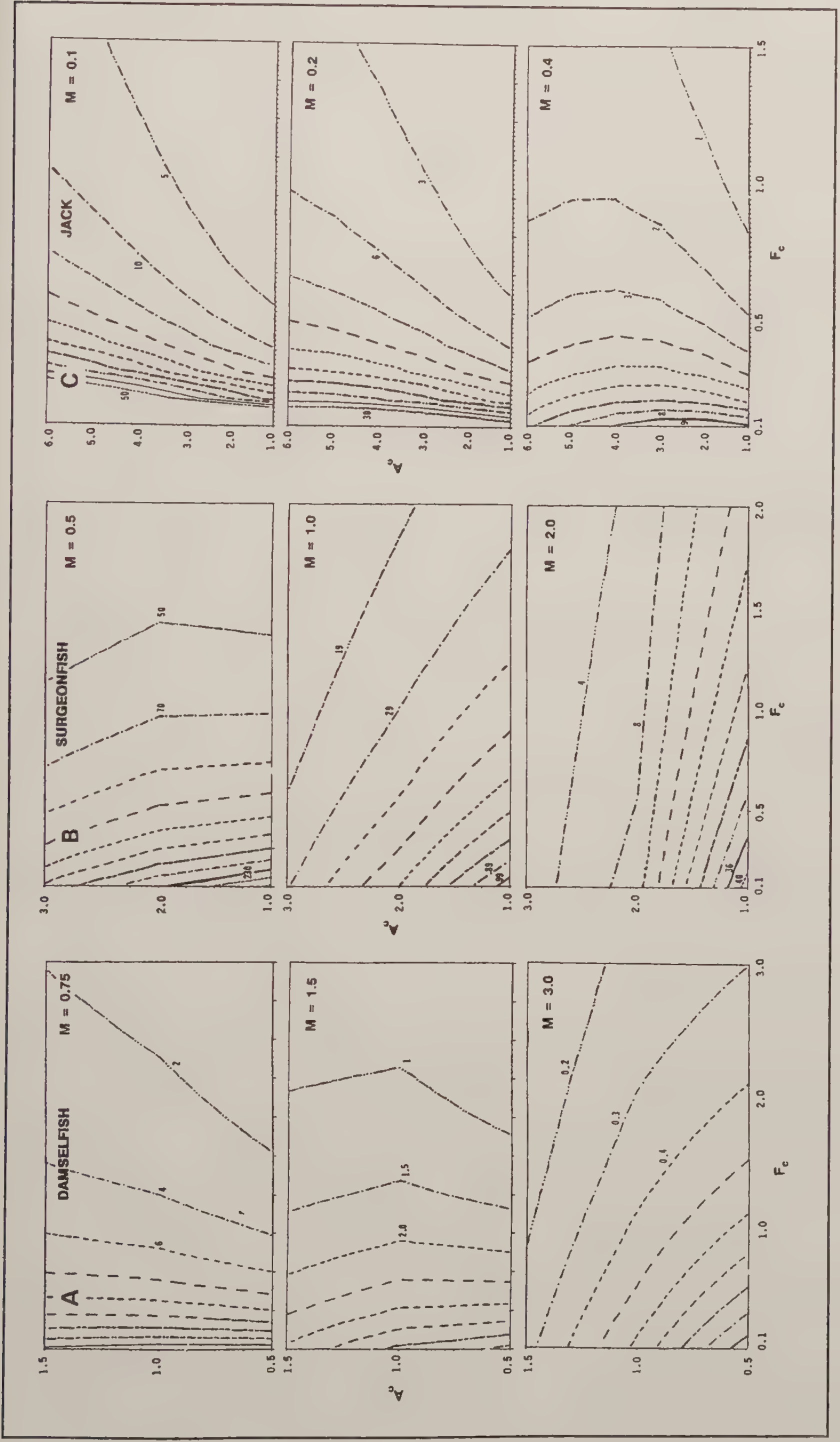

Figure 4

Stock biomass per recruit ($B/R$) surfaces as a function of fishing mortality rates ($F_c$) and age-at-recruitment to the fishery ($A_c$) for (**A**) damselfish (in grams), (**B**) surgeonfish (in grams), and (**C**) the jack (in kilograms).

Table 3

Equilibrium $B/R$ (total biomass per recruit) values without any refuge at select combinations of $A_c$ (age-at-first-capture), $M$ (natural mortality rate), and $F_c$ (fishing mortality rate) for each of the three fish types. See text Methods, Table 1, and footnotes to Table 2 for basis of chosen $A_c$ and $M$ values. $F_c$ was evaluated at values equal to $0.5M$, $M$, and $1.5M$. $B/R$ at the most reasonable (midpoint) values of $A_c$ and $M$ are emphasized in bold and underlined type, respectively, and the relative influences of $A_c$, $M$, and $F_c$ on $B/R$ are noted. $A_r = 0.5$ year (damselfish) and 1.0 year (surgeonfish and jack).

| | | | | | | | | | |

| | $M > F_c > A_c$ | | | | | | | | |

even larger countering effect (Fig. 5). The effect of compensatory rate adjustments apparently varied with fish type in a manner not directly related to fundamental transfer rate. When the surgeonfish and jack were each evaluated using $T_{1s} = 0.1$ as the fundamental rate, compensatory dampening in the rate of $SSB/R$ gain at larger refuge sizes was less for the surgeonfish (Fig. 5A) than for the jack (Fig. 5B).

## Discussion

### MFRs and enhanced Y/R

Simulations to date suggest that MFRs have the potential to augment $SSB/R$, but enhance $Y/R$ little, if at all, in adjacent non-closed areas (Polacheck, 1990; the present study). The only empirical study to date was inconclusive: Alcala and Russ's (1990) observations of an effect on reef fish catches adjacent to the Sumilon Island reserve were from a series of years in which the reserve operated and from only one year of reduced catches that began 18 months after the reserve's protected status ended. Catches were dominated by one taxon (fusiliers, family Caesionidae; 65% of total) that used the reef for nocturnal shelter but whose zooplankton prey may have been unrelated to reef area (Alcala and Russ, 1990). Brief changes in yield, rather than $Y/R$, particularly on a small (0.5 km$^2$) spatial scale, may represent nonequilibrium phenomena (e.g., lagged effects on adult abundance resulting from a localized change in recruitment). Alcala and Russ's (1990) observations therefore are not necessarily inconsistent with simulation results (see Russ et al., in press).

Clearly, additional empirical measures are needed for $Y/R$ as well as $SSB/R$ of fishery resources in exploited regions adjacent to MFRs. For the present discussion, however, this paper will focus on simulated $SSB/R$ results.

### Relative influences of input parameters

Growth rate is a major influence of biomass accrual within refuges (Polacheck, 1990), as fast-growing fish can elaborate more surplus production (yield) per unit time and unit area of refuge than can slow-growing fish. And since growth and mortality rates are linked, it is not surprising that mortality rate is important, as fishes with a higher natural mortality can support fisheries in which they are harvested more heavily and earlier in life than can fishes with a lower mortality rate.

In the basic yield model, the effects of natural mortality and level of exploitation overwhelm those of age at first capture. Proportional changes in rates obviously have larger effects than equal-sized changes in the time period over which the rates apply. Of greater interest here are the relative magnitudes of the effects

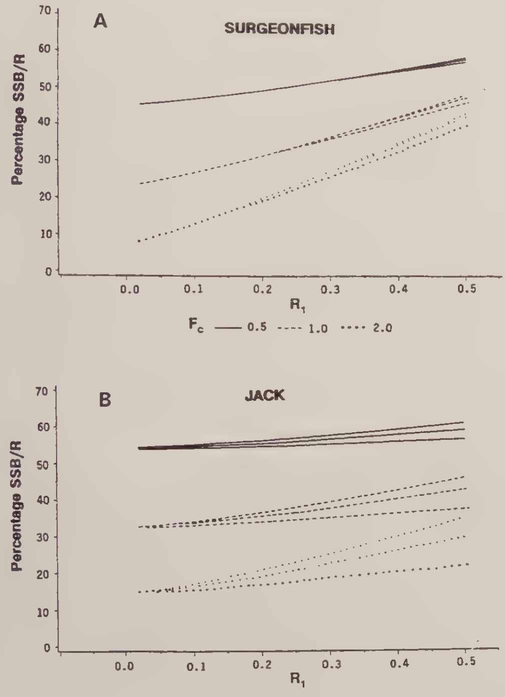

**Figure 5**

Percentage changes in spawning stock biomass per recruit (*SSB/R*) as a function of refuge size ($R_1$), fundamental transfer rate ($T_{1s}$), and two levels of density-dependent, compensatory adjustment of this fundamental rate: (**A**) surgeonfish ($T_{1s}$ = 0.1); (**B**) jack ($T_{1s}$ = 0.1). Within each triplet of lines, the upper, middle, and lower line depicts the unadjusted, adjusted 0.125-power, and adjusted 0.5-power rate, respectively.

of ages at sexual maturity and first capture, versus those of refuge size and transfer rates. I suggest that the former can have large influences for relatively short-lived, fast-growing species like the surgeonfish for which changes in age at first capture of only ±1 year represent a large fraction of its life span.

Circumstantial evidence suggests that the relative ages at sexual maturity and first capture can be important. Prior evaluations of the potential for MFRs to conserve the *SSB* of overfished commercial stocks (e.g., red snapper, *Lutjanus campechanus*) have concurrently considered other management safeguards, such as size limits in the non-closed area (Plan Development Team, 1990). However, nearshore reef fishes subject to recreational harvest are often fished at sizes and ages considerably less than those at sexual maturity, even on moderately populated islands (e.g., the island of Hawaii; Hayes et al., 1982). For reef fishes near densely populated areas where exploitation is likely to be intense on pre-reproductive fish, the potential for MFRs to enhance *SSB/R* may be severely compromised, even at closure sizes that are as large as is practical (e.g., 25%).

### Compensatory emigration

Density-dependent increases in the fundamental transfer rate can in essence depress potential gains in *SSB/R* in a manner analogous to that of a higher but constant fundamental transfer rate. The observation that gains in *SSB/R* at increasingly large refuge sizes were strongly offset by compensatory movements in the jack, but not in the surgeonfish, perhaps reflects the jack's slower growth rate, greater longevity, and lower mortality rate. Longevity, per se, may be important, because the model that was used to describe compensatory emigration is dependent upon time as well as age.

### SLOSS effects on MFR function

Simberloff (1988) reviewed the SLOSS concept and the meager results to date regarding whether multiple, small reserves function the same as single reserves of equal total size. Historically the issue of SLOSS has been applied to the preservation of threatened and endangered species or the conservation of biotic diversity (Bell and Boecklen, 1990, but see Goeden, 1979). It is increasingly apparent that meaningful stewardship of the environment and its biota extends beyond these simple (although often difficult to implement) criteria. Overexploiting an ecosystem's productivity by overfishing (Russ, 1991) is just as detrimental as recruitment or growth overfishing.

Bohnsack (1991) recently applied the SLOSS concept in a review of the function of artificial reefs. Obviously MFRs also can be evaluated in terms of SLOSS—the question then may be, "Do several small reserves potentially enhance *SSB/R* to the same extent as one reserve of equivalent total size?" A realistic example may be the relative fishery enhancement potential of ten 1% closures versus one 10% closure. Establishing a MFR of 10% may be impossible on a heavily populated island (like Oahu, Hawaii) where shoreline development is near saturation. The siting of multiple, smaller refuges, each about 1% of the total area, may be feasible, however. But can a total closure of realistic size (10%) be beneficial, and can the potential of ten 1% closures approximate it?

The simulation results suggest that a total closure of 10% may enhance the spawning stock of a fast-growing, moderately vagile reef species such as surgeonfish: at a fishing mortality rate ($F_c$) of 1.0 (equal to $M = 1.0$), $SSB/R$ can be increased by about 24% over the no-closure case for an MFR of 10%, if the lower bound of $T_{1s}$ (0.10) is used as the fundamental emigration rate. By using the higher bound for $T_{1s}$ (0.5) and an $F_c$ still at 1.0, $SSB/R$ is increased by 12% for the single 10% closure.

The overall contribution of multiple, small closures will be less, however, than that of one closure of equal total size, in inverse proportion to the increase in the total perimeter of (hence dispersal from) the multiple closures. (This follows from the general rule that smaller reserves have greater perimeter-to-area ratios than larger reserves of equivalent shape [Schonewald-Cox and Bayless, 1986].) In our example, the total perimeter of ten 1% closures is about three times ($\sqrt{10}$) that of one 10% closure. Hence, for a given fundamental transfer rate, the actual transfer rate will be appreciably greater, and the additive contribution of ten 1% closures to $SSB/R$ will be several times less, than that of one 10% closure. Multiple 1% closures might translate to an actual emigration rate approaching 0.5 for a surgeonfish that is moderately vagile ($T_{1s}$ = 0.1–0.25) relative to an MFR of 10%.

For the preceding arguments to hold, we must further assume that the multiple closures will not interact spatially. It seems reasonable though that for post-settlement stages of species with low fundamental transfer rates, ten 1% reserves may function independently if well-spaced, perhaps even on a relatively small (e.g., 100-km perimeter) island such as Oahu, Hawaii.

For simplicity, SLOSS arguments generally ignore the interactive effects of refuge shape and size. However, habitat geometry (shape as well as size) importantly influences dispersal into and from a habitat, regardless of whether an organism's movements are home-ranging or free-ranging (Stamps et al., 1987). Edge "permeability" (i.e., whether a reserve is sited within a larger area of homogeneous "soft-edged" habitat or is a functional island surrounded by discontinuous "hard-edged" habitat) also significantly affects dispersal (Buechner, 1987; Stamps et al., 1987). Small increases in edge permeability have disproportionately large effects on dispersal when boundaries are hard, whereas habitat shape exerts a controlling influence on dispersal when boundaries are soft (Buechner, 1987; Stamps et al., 1987). For shoreline-bounded reef closures, the shape of the MFR is clearly more important to residential reef fishes if the MFR is sited within a larger region of similar habitat than if different habitats (e.g., extensive sand channels) are used to provide its physical boundaries.

### Future research

The overall net effect of the diverse compensatory and depensatory factors that may influence the movement patterns of fishes into and out of MFRs is beyond even semiquantitative appraisal at present. Major advances in our understanding of the function of MFRs await development of techniques that describe the fundamental transfer rates of fishes (Polacheck, 1990) and that further estimate the changes in movement rates that may occur as densities change over time. The results of my preliminary analyses suggest that future studies should focus on fast-growing, moderately vagile species such as many surgeonfishes, rather than reef transients or philopatriots. My preliminary conclusions should be reevaluated as more data become available for these and other types of reef fishes.

### Management potential

MFRs have the potential to enhance the biomass and spawning stock of species with rapid growth and moderate, fundamental transfer rates (Polacheck, 1990; the present paper). Many factors, however, contribute to whether this potential is likely to be realized in practice: the age schedule of harvest and the magnitude of fishing effort in the non-closed area; whether one versus a few or many MFRs of a given total area are used, thereby promoting progressively larger increases in fundamental transfer rates; and whether compensatory emigration acts to further inflate vulnerability and deflate $SSB/R$. Decisions as to the number versus size of MFRs that can be sited, given the total shoreline extent of reef available, are social issues. Size limits and fishing effort (bag limits) also are subject to their own management politics, and MFRs will not make them obsolete. Although the fast growth and moderate movement rates of certain tropical reef fishes predispose them to benefit from refuges, it is unlikely that the establishment of MFRs alone, without complementary regulation of effort and the size composition of catch in non-closed areas, can augment the SSB/R of fishes on heavily exploited island reefs.

## Acknowledgments

I thank M. Yong and especially D. Tagami for help with programming code. J. Polovina and D. Somerton offered stimulating discussion, and J. Bohnsack, J. Polovina, T. Ragen, C. Roberts, G. Russ, D. Somerton, and an anonymous reviewer provided constructive criticisms of draft manuscripts. T. Polacheck graciously provided a copy of his computer program and assisted

with program re-specifications. I accept full responsibility for any remaining errors.

**Abstract.** – Size-specific fecundities of spiny lobster *Panulirus marginatus* were compared for two time-periods: pre- and early exploitation or "before" (1978–81), and post-exploitation or "after" (1991). Fecundity was further evaluated within each time-period at two collection sites that represented the major lobster fishing grounds (Maro Reef and Necker Island) in the Northwestern Hawaiian Islands. Complementary data on egg size and spawning-frequency index were compared between study sites and time-periods.

Study sites and time-periods had no observable effects on egg size or spawning frequency, and there was no temporal effect on fecundity at Maro Reef. Fecundities at the two sites differed, however; "after" size-specific fecundity was an estimated 16±9% greater than "before" fecundity at Necker Island. Observations suggest that the recent increase in fecundity at Necker Island may reflect a compensatory (density-dependent) response to greater exploitation at this site. Results are discussed in terms of evidence for density-dependent responses in other, exploited spiny lobster stocks.

Manuscript accepted 19 August 1992.
Fishery Bulletin, U.S. 91:1-7 (1993).

The spiny lobster *Panulirus marginatus* (Quoy & Gaimard) is endemic to the Hawaiian Archipelago and Johnston Island (Brock 1973, Uchida et al. 1980). This species supported a major commercial fishery in the main Hawaiian Islands (MHI) prior to the rapid increases in demand after World War II (Uchida et al. 1980). Not until the expansion of the fishery into the Northwestern Hawaiian Islands (NWHI) began in 1977 did the species again support a valuable commercial enterprise, complemented with bycatches of slipper lobster *Scyllarides squamosus* (H. Milne-Edwards) and *S. haanii* (De Haan). A fishery management plan was created in 1983 to regulate the fishery based on minimum size limits and limited entry.

Prior to 1990, annual landings averaged 1–2 million spiny lobster worth US$4–6 million ex-vessel. Beginning in 1990 and continuing until the fishery closure in early 1991, however, landings fell heavily, equaling one-fifth of the long-term average (Landgraf 1991). These decreases reflected real declines in abundance, as both research and commercial catch per trap-haul (CPUE) similarly declined (Landgraf 1991). The present belief is that recent declines in the spiny lobster CPUE reflect a combination of continued, heavy exploitation and the occurrence of a series of poor year-classes, particularly at Maro Reef, one of the two major NWHI fishing grounds (Polovina 1991).

Recent research by Polovina (1989) has indicated that a density-dependent decrease in the size-at-onset of egg production occurred in NWHI spiny lobster from 1977 to 1986–87. Additional types of compensatory responses to lower population densities may be operative and may have a major influence on the dynamics of these lobster populations, but data are lacking (Polovina 1989). Included among these compensatory mechanisms is an increase in size-specific fecundity, a phenomenon suggested for other species of spiny lobsters (Chittleborough 1976 and 1979, Beyers & Goosen 1987, MacDiarmid 1989).

With the *a priori* prediction that size-specific fecundities might have increased for NWHI spiny lobster during the recent period of low population densities, we initiated a study of its fecundity and related reproductive life history. Prior to our study, little quantitative information existed on the fecundity of this species, and data were limited to the waters off Oahu in the MHI (Morris 1968, McGinnis 1972). Our objective is to compare the size-specific fecundities of NWHI spiny lobster between two time-periods: an early or pre-exploitation (hereafter referred to as "before") period in 1978–81, and a postexploitation ("after") period in 1991, when population densities had declined to a fraction of their pre-exploitation level.

## Methods and materials

### Specimen collection

Spiny lobster were collected using baited commercial traps at Maro Reef and on the offshore bank of Necker Island, the second of the two major NWHI fishing grounds (fig. 1, Polovina 1989). Lobsters were trapped during multiple cruises aboard chartered commercial vessels and the NOAA ship *Townsend Cromwell* during the summertime (May–August) breeding seasons of 1978–81 (the "before" period) and on a single cruise by the *Townsend Cromwell* during June–July 1991 ("after"). Commercial traps fished for a standard (overnight) soak period were used at each site during both time-periods. Specimens were similarly handled aboard the chartered vessels and the *Townsend Cromwell*.

### Sample processing

Lobsters were sexed, carapace length (CL) measured, and the egg developmental stage of egg-bearing ("berried") females scored as either Stage 1 (orange = freshly extruded), Stage 2 (brown = late development), or Stage 3 (white = hatching imminent). The CL, defined as the distance along the middorsal line from the transverse ridge between the supraorbital spines to the posterior margin of the carapace, was measured to the nearest 0.1 mm. Berried female specimens were either processed fresh in the ship's wet lab or flash-frozen (damp) aboard ship for processing ashore.

In the laboratory, brood sizes were estimated using Stage-1 females whenever possible so as to minimize the effect of potential egg loss (Morgan 1972, Annala & Bycroft 1987). The eight pleopods including egg clusters (setae bearing the egg masses) were separated by dissection and placed on absorbent paper towels. Egg clusters were then stripped off the pleopods onto preweighed weigh boats. Each individual female's total egg complement was weighed (damp weight to 0.1 mg) and then reweighed following determination of egg subsample weights; these two weighings were then averaged to provide a measure of the total egg mass. Random subsamples comprising a minimum (by weight) of 1% ($\bar{x}$=1.5%) of the female's total egg mass were weighed (0.1 mg) and later enumerated to estimate fecundity ($F_t$=total number of eggs) by proportion:

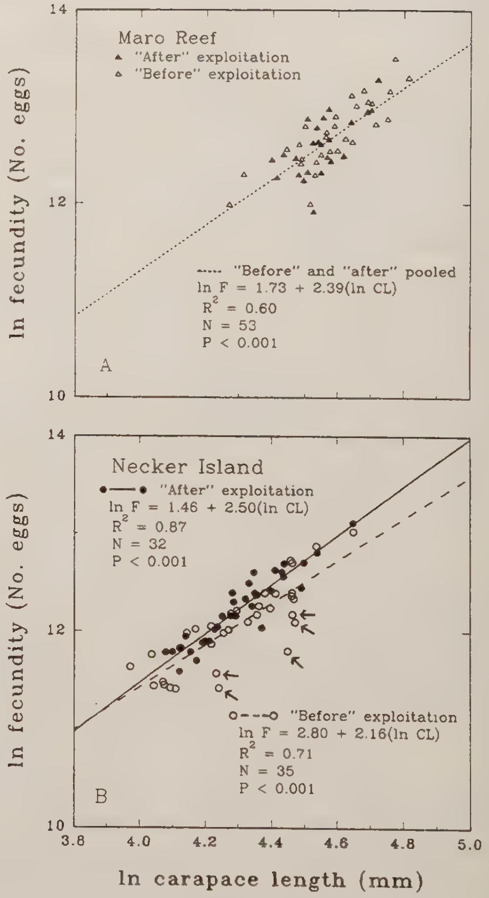

**Figure 1**

Scatterplots, least-squares regressions, and regression statistics for ln fecundity (number of eggs) versus ln carapace length (in mm) for berried female spiny lobster *Panulirus marginatus* trapped at two locations in the Northwestern Hawaiian Islands. **Maro Reef (top).** Data for the "before" (1978–81) and "after" (1991) periods are pooled for the regression analysis but plotted separately; one extreme outlier was omitted (see Results). **Necker Island (bottom).** Data for the "before" and "after" periods are plotted and analyzed separately. Arrows indicate the five most-extreme "before" data that were deleted in a re-analysis of the data (see Results).

$$F_t = F_s \cdot \left(\frac{W_t}{W_s}\right),$$

where $F_s$ = number of eggs in subsample, $W_s$ = weight of egg subsample, and $W_t$ = total weight of eggs. Some frozen-thawed egg masses were fixed in 4% formaldehyde for 1 month to harden eggs prior to weighing and counting. A single subsample was used to characterize the fecundity of each "before" specimen. Three replicate subsamples were used to estimate the sampling error of "after" fecundity determinations; the three pooled subsamples provided the best estimate of "after" fecundity. Total eggs were counted for one of the "after" specimens to gauge the accuracy of the weighing and counting procedures.

Egg sizes were estimated to complement the fecundity data. For a subset of both "before" and "after" Stage-1 specimens, a minimum of 25 eggs per female were randomly chosen and measured (random axis, at 50×) using a dissecting microscope with calibrated eyepiece micrometer.

Total egg production is the product of the number of eggs produced per spawning (brood size) and the number of spawnings. For females above threshold body sizes at onset of egg production at each of the sites during the two time-periods (Polovina 1989), we indexed spawning frequency based on the relative frequencies of berried (to total) females present in historical catch data of the Honolulu Laboratory. We used records of catches made at Maro Reef and Necker Island on summertime cruises during years within pre- and postexploitation periods when sufficient data were available (1977, 1988–91).

### Statistical analysis

Analysis of covariance (ANCOVA, SAS Proc GLM; SAS 1985) was used to compare mean fecundities between sampling periods; CL was used as a covariate to adjust for potential body-size differences between periods. As justified, central tendencies in fecundity were compared between periods ("before," "after") using least-square means (LSM) and their standard errors (SEM). Period and site (Maro Reef, Necker Island) were evaluated as class variables. Student's *t*-test, with degrees of freedom adjusted (as necessary) by Satterthwaite's approximation for unequal variances (Bailey 1981), was used to compare indices of spawning frequency between periods.

## Results

### Size-fecundity relationships

Paired CL and fecundity data were available for 54 spiny lobster from Maro Reef. At Necker Island, there were 67 analogous data pairs (Appendix A). Over 90% of the "before" specimens had Stage-1 eggs, and Stage-2 eggs were equally distributed among specimens from the two sites. Incidence of Stage-2 eggs appeared higher in the "after" samples from Maro Reef (8/24=33%) than in the analogous samples from Necker Island (3/32=10%). No lobsters with Stage-3 eggs were collected during either time-period. The coefficient of variation [$CV=(SD/\bar{x})\cdot 100$] of the triplicate "after" fecundity estimates was about 2%. The accuracy of the mean of the two weighings of an entire egg mass was within 4% of a total count.

At Maro, slopes were indistinguishable between periods, regardless of whether an obvious outlier (whose residual deviated 8.5% from its predicted value) was included (ln CL × period interaction: $F_{1,50}=0.06$, $P=0.81$) or was deleted from the analysis ($F_{1,49}\leq 0.01$, $P>0.99$). Slopes also were indistinguishable between the two periods at Necker Island ($F_{1,63}=1.17$, $P=0.28$).

Intercepts did not differ between periods at Maro Reef ($F_{1,50}=0.22$, $P=0.64$), but the period (intercept) effect at Necker Island was significant ($F_{1,64}=10.17$, $P=0.002$). Greater size-specific fecundity in the "after" period at Necker Island persisted, even if the five most-extreme "before" values (noted by the arrows in Fig. 1) were deleted and the analysis rerun ($F_{1,59}=4.40$, $P<0.05$). Using all available data, the power (1 minus Type-II error) of the test for period differences at Necker Island was 84%, for a critical Type-I error of 5% ($\alpha_2=0.05$).

CL significantly influenced fecundity at both Maro Reef ($F_{1,50}=70.6$, $P<0.001$; Fig. 1) and at Necker Island ($F_{1,64}=215.6$, $P<0.001$; Fig. 1). After adjustment for period differences in CL, the fecundity of lobsters at Necker Island was an estimated 16±9% greater during the "after" versus the "before" period (LSM±SEM of lnF = 12.224±0.034 and 12.072±0.033, respectively). Unlike the case at Necker Island, mean fecundity at Maro Reef differed only by <3% between the "before" and "after" periods (LSM±SEM = 12.680±0.041 and 12.651±0.046, respectively).

### Egg size

The median egg diameters of 22 females collected from Maro Reef and Necker Island during the "before" period were 0.58–0.69 mm. The analogous data for 53 "after" females were 0.61–0.73 mm, with a grand median of 0.66 mm.

Slopes of female body size/egg size (median diameter) relations were indistinguishable between sites (CL × site interaction: $F_{1,51}=0.55$, $P=0.46$). Intercepts also were indistinguishable: egg size was uninfluenced by site ($F_{1,52}=2.75$, $P=0.10$). Carapace length had no effect when sites were evaluated separately ($F_{1,52}$=0.11, $P$=0.75). However, female size significantly but weakly ($R^2$=0.08) affected egg size when data for the two sites were pooled (CL effect: $F_{1,53}$=2.104, $P$=0.04; median egg diameter = 30.2 EPU+0.039 $CL_{mm}$; $N$=55; EPU= 0.0197 mm).

### Spawning frequency

The relative frequency of berried/total adult females collected at Maro Reef and Necker Island during the summer of 1988 ($N$=3085 adult females), 1990 (1198), and 1991 (1165) was 0.246±3.401 ($\bar{x}$±1SD, $N$=6 site-year combinations). This index of the spawning frequency of females did not differ (t'=0.01, $P$>0.9) from 0.230±0.510, the estimated frequency for 3037 females collected during the summer of 1977 ($N$=2 site-years).

## Discussion

### Fecundity-body size relations

Exponents of the curvilinear, $F=a\cdot CL^b$, relations observed in this study ranged from 2.16±0.241 (statistically equal to 2.0) to 2.50±0.175 ($2.0<b<3.0$; Fig. 1). Perhaps both area of egg-bearing surface and volume (female body mass) influence fecundity in this species. Prior data on size-specific fecundity for an Oahu population of *P. marginatus* allow us to estimate the exponent in the equation $F=a\cdot CL^b$ as 2.96±0.31SE ($N$=11; table XV, Morris 1968).

A variety of linear:cubic relationships are available for other spiny lobster species. The following values of the exponent b in the power equation are either known or calculable for: *Panulirus interruptus* (1.0, Lindberg 1955), *P. homarus* (1.0, Berry 1971), *P. cygnus* (1.0, Morgan 1972); *Jasus verreauxi* (1.0, Kensler 1967), *J. edwardsii* (1.0, Kensler 1968; 3.01, McDiarmid 1989; 2.11–3.75, Annala & Bycroft 1987), *J. lalandii* (1.0, Beyers & Goosen 1987 and Pollock 1987; 3.58, Zoutendyk 1990), *J. tristani* (1.0, Pollock & Goosen 1991), *Nephrops norwegicus* (2.35, Thomas 1964 in Aiken & Waddy 1980). Best fits thus vary from linear to cubic both among species and among geographic populations within species. The only apparent pattern is the generally linear relationship between length and egg number in other *Panulirus* spp.

### Parameter interrelations

Although size-specific fecundity clearly changed between the "before" and "after" periods of exploitation for Necker Island lobster, neither egg size nor spawning frequency appeared to differ between the two sampling periods at either study site. Theoretically, size-specific fecundity might be expected to co-vary with egg size and spawning frequency (Gadgil and Bossert 1970). However, in many organisms, offspring size and number often do not track one another simultaneously or to an equivalent extent (Capinera 1979, Roff 1982). Therefore, our observation that egg size did not co-vary with egg number in *Panulirus marginatus* should not be surprising. Perhaps strong selection for planktonic larvae of relatively invariant body size is typical within particular populations of spiny lobster, even though average egg sizes might differ among populations of some species. This speculation is consistent with our observation that estimated egg volume varied only about 50% among female *P. marginatus* of a large range of body sizes from either site. This value is low compared with those of most marine teleosts (Bagenal 1971).

### Site and period comparisons

The site (geographic population) differences observed in this study of NWHI spiny lobster are not without precedent in other spiny lobsters. Annala & Bycroft (1987) and Beyers & Goosen (1987), for example, observed geographic differences in the size-specific fecundities of *Jasus edwardsii* and *J. lalandii*, respectively. For *J. edwardsii*, differences in size-specific fecundity were detected for populations ranging from extreme southern to northern New Zealand (Annala & Bycroft 1987). The spatial scale of the geographic pattern noted by Beyers & Goosen (1987) for *J. lalandii* was 600 km. Approximately 650 km separate Necker island and Maro Reef.

Unlike the Necker Island population, the fecundity of lobsters from Maro Reef was indistinguishable between the two sampling periods. The absence of a period effect at Maro Reef was not due to larger variance at a similar effect size (Cohen 1988); rather, the standard deviation of the residuals of lnF at Maro Reef (0.217) resembled that for Necker Island (0.206). There is the possibility, though, that size-specific fecundity has increased at Maro Reef too, but we were unable to detect it because of an artifact that particularly affected the fecundity estimates of "after" specimens from this site. Many of our "after" specimens from Maro Reef had Stage-2 eggs. Greater egg loss might have occurred during the handling of these specimens, because eggs at later stages of development may be more prone to dislodgement (Annala & Bycroft 1987). Anecdotal observations of the integrity of egg masses of the "after" females from Maro Reef suggest that, even though some additional egg loss might have occurred, it is unlikely to have been sufficient to obliterate an increase in size-specific fecundity of a magnitude similar to that observed for Necker Island lobster.

A significantly greater size-specific fecundity persisted at Necker Island in the "after" period even if the most-likely outliers from the "before" data were excluded from the analysis. This conservative re-analysis strongly suggests that period differences in the size-specific fecundities of Necker Island lobster are real. The magnitude of our best estimate of this difference (16%) further suggests that it represents a biologically meaningful change. A much more extensive series of before-and-after data would be necessary to resolve this issue beyond a reasonable doubt.

On balance, then, our data suggest that the size-specific fecundity of NWHI spiny lobster has increased at Necker Island, but likely not at Maro Reef, following a decade of heavy exploitation at both fishing grounds. Why and how can this be?

The data of Polovina (1989) suggest one possible explanation. The density-dependent decrease in mean carapace length-at-onset of egg production has been proportionately greater for female lobsters at Necker Island (10–15%, 67.8 to 57.9–60.8 mm) than at Maro Reef (6–9%, 74.8 to 68.2–70.5 mm; table 3, Polovina 1989). In 1977, the pre-exploitation densities (catch per trap-haul) of adult lobsters were higher at Necker Island ($\bar{x}$±SEM = 5.76±0.75) than at Maro Reef (3.89±0.45); yet by 1986–87, densities had declined more at Necker Island (to 2.14±1.24) than at Maro Reef (2.65±0.67; tables 1&2, Polovina 1989). By decreasing densities to a greater extent (thereby making more shelter or food resources available per lobster), it is possible that the effects of more intense cropping may now extend beyond decreased size-at-maturity to greater size-specific fecundity for Necker Island lobster.

Other factors besides exploitation might be somehow influencing the density and size-specific fecundity of *P. marginatus* at Maro Reef. Relatively few small lobsters were present at Maro Reef compared with Necker island during either of the time-periods used in our fecundity comparison (Polovina 1989; Fig. 1). Even so, disproportionately low recruitment at Maro Reef during 1986–88 might have recently exaggerated long-term baseline differences in the body-size distributions of exploitable *P. marginatus* at the two banks (Polovina & Mitchum 1992). Of the several possible reasons for higher pre-exploitation densities at Necker Island (more productive bottom habitat, fewer adult lobster predators), none is presently substantiated. Studies are in progress to evaluate the quality and distribution of bottom habitats among Maro Reef, Necker Island, and other NWHI lobster grounds.

### Density-dependent reproduction in lobsters

Density-dependent changes in egg production have been described or suggested for several other species of spiny lobster. Examples include changes in the number of spawnings (duration of spawning season) for individual females (Chittleborough 1976, 1979) as well as increases in size-specific fecundities (Thomas 1964, Beyers & Goosen 1987, MacDiarmid 1989) in response to lower population densities or otherwise greater food availabilities. Body size at onset of sexual maturity has responded in qualitatively different fashion to changes in lobster densities among different populations and species of lobsters. Several studies of *Jasus lalandii* (e.g., Pollock & Goosen 1991) have observed smaller body sizes at first maturation in stunted or physiologically stressed, high-density populations. As mentioned previously, Polovina (1989) has demonstrated the opposite response to reductions in adult densities resulting from exploitation. A fundamental, biological difference is whether size-at-maturity is an age- or size-dependent trait for a particular species and population. It is reasonable to expect species differences in the determination of maturation, and comparative studies of the mechanisms regulating the onset of maturation in different spiny lobsters would be informative.

### Statistical considerations

Several studies have evaluated, but been unable to detect, geographic variations in fecundity (Thomas 1964, Morgan 1972). The study by Morgan (1972) represents a case in which sample sizes were small and power was low despite nontrivial effect sizes. Future studies of lobster fecundity should report statistical power, especially when tests are unable to reject null hypotheses of no difference among populations.

## Acknowledgments

We thank F. Parrish for providing the specimens used for the "after" characterization; B. Lau for assisting in the development of laboratory protocols; K. Landgraf for help in locating files; W. Haight for deciphering historical catch records; J. Polovina for comments on analysis design; and D. Aiken, J. Polovina, R.M. Smith, and J. Uchiyama for constructive criticisms of draft manuscripts.

# Effects of dolphin group type, percent coverage, and fleet size on estimates of annual dolphin mortality derived from 1987 U.S. tuna-vessel observer data

**Elizabeth F. Edwards**
**Christina Perrin**
Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA
P.O. Box 271, La Jolla, CA 92038

**Abstract.**–Amendments enacted in 1988 to the U.S. Marine Mammal Protection Act of 1972, coupled with changes during the 1980's in the composition of the international purse-seine fleet fishing "on dolphin" for yellowfin tuna in the eastern tropical Pacific (ETP), motivated a simulation experiment to assess the effects of fleet size and observer coverage level on estimates of cumulative annual mortality for dolphin stocks, where data quality differed greatly between stocks. Results from this simulation study provided a basis for subsequent U.S. legislation regarding criteria for comparing dolphin mortality rates of U.S. vs. non-U.S. fleets fishing in the ETP, pursuant to regulations governing import of tuna from this area.

Accuracy and precision of mortality estimates were influenced very strongly by data quality (dolphin group type) and moderately strongly by fleet size and level of observer coverage. Because neither fleet size nor dolphin group type can be controlled by a sampling program, desired levels of accuracy and precision in estimates of dolphin mortality can be achieved only by manipulating the level of observer coverage. The unexpectedly strong effect of dolphin group type implies that to protect all groups equally, observer levels should be chosen to accommodate the dolphin group type exhibiting the poorest-quality data.

U.S.-registered tuna purse-seiners in the eastern tropical Pacific Ocean (ETP) inadvertently kill dolphins during fishing operations (DeMaster et al., 1992). Since 1972 this kill has been monitored by scientific observers accompanying seiners on routine fishing trips. The kill data are monitored to determine whether annual quotas have been reached for dolphin mortality overall, and for several specific stocks of dolphins. If any quota is reached, fishing must cease on the affected stock for the remainder of the calendar year. Since 1989, the data have also been used to determine annual dolphin mortality rates for comparison with non-U.S. fisheries[1].

Prior to 1987, this kill monitoring was accomplished by observers on 30–50% of the trips made by U.S. purse-seiners during a given year. Thus, mortality was estimated rather than measured directly. In the absence of any alternative (i.e., higher rates of observer coverage), the accuracy and precision of these estimates were assumed to be adequate. This assumption was acceptable at the time because the U.S. fleet was large and generated many data. About 100 vessels fished the eastern tropical Pacific Ocean (ETP) each year, each vessel making two to five trips of about three-months duration each.

The situation changed dramatically in the 1980's when, for a variety of reasons (Sakagawa, 1991), the U.S. fleet began to decrease 20–30% per year, decreasing from over 90 vessels in 1981 to about 10 vessels in 1992. This decrease in size of the U.S. fleet was offset by a reciprocal increase in number of non-U.S. vessels fishing in the ETP. This increase has been dominated by Mexican vessels (fleet size exceeding 50 vessels by 1990) but also includes smaller fleets from several other nations. These smaller fleets range in size from 1 to about 20 vessels (IATTC Annual Reports, 1980–1991). In addition to these changes in composition of the international fleet, amendments passed in 1988 to the U.S. Marine Mammal Protection Act stipulated that yellowfin tuna caught in the ETP could be imported from non-U.S. countries only if mortality rates for those countries were comparable to U.S. kill rates.

These events created a strong incentive to evaluate the effects on mortality estimates of varying observer coverage levels and fleet sizes. Because the new regulations pertained to some individual stocks in addition to dolphin mortality overall, the previously uninvestigated effect of dolphin group type was also of interest.

---

[1] The mortality estimator used in these simulations (kill/day) is not the same estimator used currently (1993) to determine mortality comparability (kill/set). The reasons for this appear in the methods section.

Manuscript accepted 4 June 1993.
Fishery Bulletin 91:628–640 (1993).

The U.S. data set for 1987 provided a unique opportunity to investigate these effects. That year, for the first time, observers accompanied nearly 100% of trips by U.S.-registered purse-seiners to the ETP. By subsampling the 1987 data set, various observer levels and fleet sizes could be simulated and their effects on dolphin mortality estimates studied. In the absence of any other available data, these data were taken by NMFS as roughly representative of the international fleet. The simulation results guided subsequent legislation regarding mortality comparability criteria for non-U.S. fleets in the ETP.

Total annual mortality estimates are presented here for three dolphin groups (all stocks combined): spotted dolphin (*Stenella attenuata*); whitebelly spinner dolphin (*Stenella longirostris longirostris*); and common dolphin (*Delphinus delphis*). These three groups represent the range of data types (good, intermediate, and poor in quality) in the 1987 data set, and are generally representative of data types collected every year that may be affected by variable fleet sizes and levels of observer coverage in future fishing years.

Accuracy and precision of the mortality estimates are presented in terms of relative bias and coefficient of variation. Frequency distributions and analytic confidence intervals are examined for underlying patterns in mortality data responsible for generating observed patterns in accuracy and precision.

## Methods

### Data

During 1987, 34 U.S.-registered purse-seine vessels carrying certificates that permitted fishing "on dolphins" made a total of 134 fishing trips to the eastern tropical Pacific Ocean (ETP). Of these vessels, 33 made 124 trips that were observed by either a National Marine Fisheries (NMFS) or an Inter-American Tropical Tuna Commission (IATTC) technician. These 124 observed trips comprised the entire population of trips for this study. They accounted for 93% of all trips and 96% of all days spent at sea in the ETP by U.S.-registered tuna purse-seiners during 1987. Trips made by individual vessels within fleets were considered replicates and observed trips were assumed to represent unobserved trips accurately. Data consisted of records of date, time, trip number, set number, and kill per set.

Between 4 and 20 vessels carrying observers departed each month during 1987 (Fig. 1). Approximately the same number (although not necessarily the same vessels) of observed vessels (about 30) fished in the ETP during any given month (Fig. 2). Just over half the trips (65/120) lasted about three months. Trip duration ranged from one to six months (Fig. 2). Number of trips incurring mortality of each dolphin group type ranged from 93 (offshore spotted dolphins; Fig. 3) to 12 (common dolphins).

Dolphin mortality data were not stratified geographically, despite the demonstrated efficiency of this stratification scheme (e.g., Hall and Boyer, 1986) because it can be applied only when data sets provide reasonable numbers of reasonably homogeneous data per stratum. Data tend to be so variable for the less frequently killed groups, such as common dolphins, that mortality estimates tend to be very imprecise (and infrequent) even without stratifying data. This is likely to be a problem for all dolphin types for small fleets in every year[2].

Data quality differed between group types in both frequency and extent of kill. Data for offshore spotted dolphins were the "best" in terms of being most plentiful and most evenly distributed between trips collecting data. The frequency distribution of kill per day per trip (i.e., number of dolphins killed per number of days at sea, for a given trip) is relatively smooth (Fig. 3). Most trips killed about 0.5 dolphins per day, a few

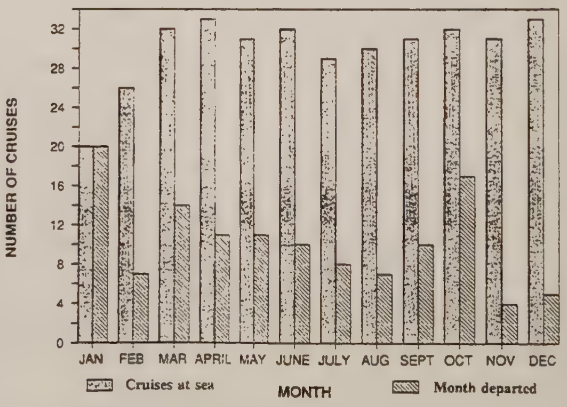

Figure 1
Number of observed U.S.-registered tuna purse-seine vessels at sea, and number of observed vessels leaving port each month during 1987.

---

[2] At the time this study was conducted (1988–1989), there were no legal requirements for data stratification. Subsequent to this study, the U.S. Congress enacted legislation (Federal Register Notice Vol. 54, #43, Tuesday March 7, 1989; 54 FR9438-9451) requiring stratification of data for annual mortality estimates into three geographic strata and two dolphin groupings (common dolphins, and all other dolphins).

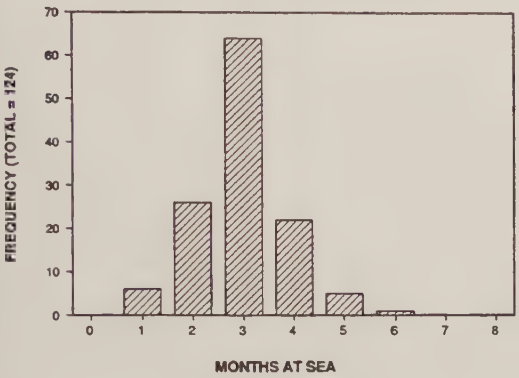

**Figure 2**
Months spent at sea per trip by U.S.-registered tuna purse-seine vessels carrying observers during 1987.

trips killed no spotted dolphins, and trips with higher kills occurred with decreasing frequency. Data for whitebelly spinner dolphins were intermediate in quality. They were fewer but still relatively smoothly distributed. About half the trips killed no whitebelly spinner dolphins, but of those incurring mortality, most trips were responsible for about 0.1 dolphins per day. Higher kills again occurred with decreasing frequency, with little evidence of extreme outliers. Data for common dolphins exhibited the worst quality, being both sparse and very unevenly distributed. Of the 12 trips incurring mortality of common dolphins, 9 killed about 0.5 dolphins per day, 2 trips killed 1–1.5 dolphins per day, while the remaining trip was responsible for about 9 deaths per day. That one trip was responsible for 67% (594/882) of U.S.-caused common dolphin deaths during 1987.

## Simulations

We first selected randomly and without replacement 5, 10, or 20 vessels from the total of 33 observed vessels (Fig. 4). We then sampled randomly and without replacement, 25%, 50%, or 75% of the trips made by each of these selected vessels, without regard to actual timing of those trips throughout the year. We did not force temporal stratification on these small fleet simulations because fleet sizes of 5 or 10 vessels generated so few data.

Vessel selections were replicated 10 times at each combination of fleet size and percent coverage. Trip selections were replicated 50 times from each of the 10 sets of selected vessels. Thus, selected vessels were the same within each set of 50 replicate samples of trips but differed between sets of 50 replicates. Trips conducted by selected vessels in each sample fleet represent the "population" of trips for that fleet replicate.

Each set of 50 replicate selections of trips from a given set of selected vessels generated 50 estimates of cumulative annual mortality (cumulative mortality through December 31). For each set of 50 estimates, we calculated the mean estimate, the coefficient of variation for the mean estimate, and the relative bias of the mean estimate. Thus for each combination of fleet size and percent coverage we generated 10 averaged estimates of annual mortality, 10 coefficients of variation, and 10 estimates of relative bias.

Because the "true" kill varied between fleet replicates depending on the particular vessels and trips selected, the average of these 10 averaged estimates (from the 50 replicates) of annual mortality is not a particularly useful measure in this study. This average represents only the average of the 10 sets of vessels that happened to be chosen for the 10 replicates of fleet size. However, the coefficients of variation and estimates of relative bias for each of the 10 averaged estimates *are* relevant indicators of the ability of the estimation process to precisely or accurately, or both, reflect the true kill, whatever it happens to be for a particular sample of vessels. Accordingly, we present results only for the averages of the 10 estimates of CV and RB generated for each combination of percent coverage, fleet size, and dolphin mortality type. We do not discuss directly the individual mortality estimates.

## Estimates

The estimates in this simulation study were derived by using the ratio estimator kill per day, rather than the more precise estimator kill per set (Lo et al., 1982; Hall and Boyer, 1986) because at the time this study was designed and executed, kill per day was still the estimator of choice for NMFS[3].

---

[3] Kill/day was used by NMFS up until 1987 when 100% observer coverage began, because the quota system required that dolphin kills be monitored continuously throughout the year rather than simply summed at the end of the year. Estimates based on kill/day can be made on a reasonably real-time basis because the day that a vessel leaves port is a readily available datum, and observers report kills by radio on a biweekly basis throughout each observed trip. Number of days fished by the entire fleet (observed plus unobserved) can then be determined relatively simply by summing the number of days at sea since leaving port, and total kill estimated as the product of total fleet days times the estimator kill/day. Biweekly estimates based on kill/set are not possible because observers are not permitted to report set data over the radio. Set data do not become available until after vessels have returned to port.

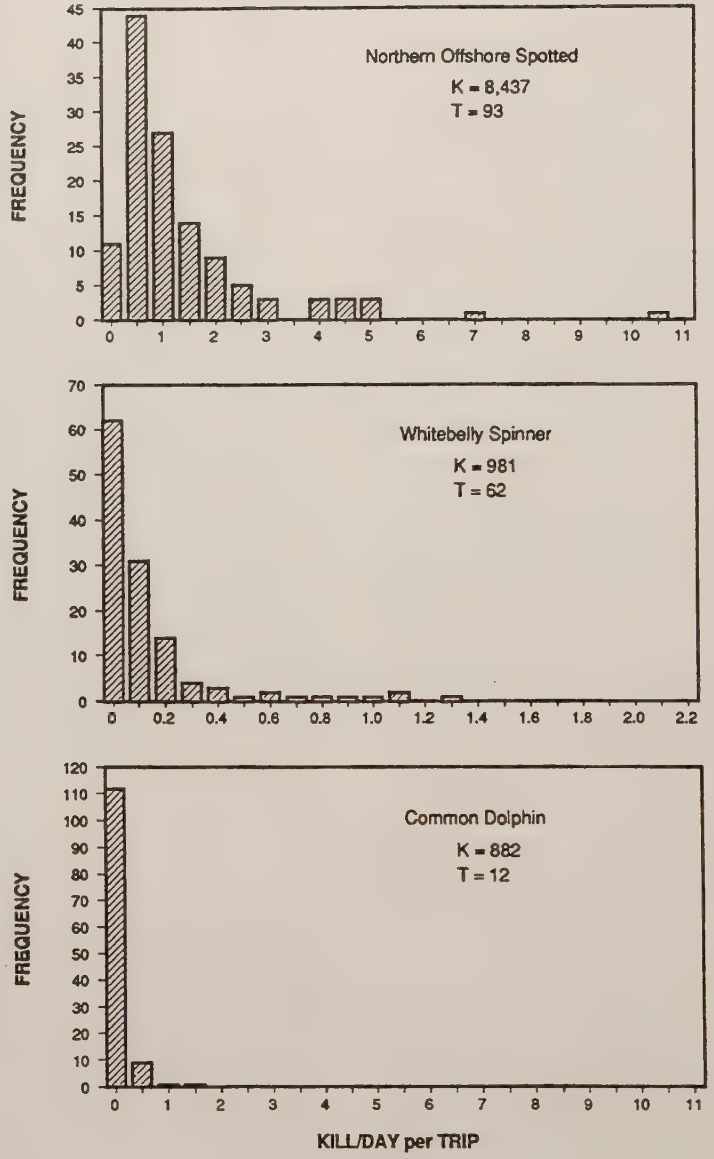

**Figure 3**

Kill per day during observed trips (124 trips total) by 33 U.S.-registered tuna purse-seiners fishing in the ETP during 1987, for three species of dolphins representing the range of mortality data types. Scales of ordinates and abscissas differ between panels. *K* is total observed kill during 1987; *T* is number of trips incurring kill.

Factors and levels included dolphin group$_i$ ($i$=1,2,3; offshore spotted, whitebelly spinner, and common dolphin), fleet size$_j$ ($j$ = 1,2,3,4; for 5, 10, 20, or 33 boats), fleet replicate$_k$ ($k$=1,..,10), percent coverage$_l$ ($l$=1,2,3; for 25%, 50%, and 75%) and percent coverage replicate$_m$ ($m$=1,...,50).

Fleet Rep (10)
TRIP "pop" (1)
TRIP "pop" (2) ....
TRIP "pop" (10)
eg. % Cov=25%
% Coverage Rep (1)
% Coverage Rep (50)
$(m_{rep} = 50)$
$\hat{K}_{1,1}$ .... $\hat{K}_{1,50}$
$\bar{\hat{K}}_1 = \left[\frac{\sum_{i}^{50} \hat{K}_{1,i}}{50}\right]$
$\bar{\hat{K}}_{10} = \left[\frac{\sum_{i}^{50} \hat{K}_{10,i}}{50}\right]$
$\bar{\bar{\hat{K}}} = \left[\frac{\sum_{j}^{10} \bar{\hat{K}}_j}{10}\right]$

**Figure 4**
Sampling procedure for simulation study.

Within each replicate, cumulative annual mortality for a given group of dolphins (*YHAT*) is estimated as

$$YHAT_{ijklm} = (K_{ijklm} / DAYS_{jklm}) * TFDAYS_{jk}$$

where $K_{ijklm}$ is the observed cumulative annual kill on all selected trips, $DAYS_{jklm}$ is the observed number of days, and *TFDAYS* is the total number of days spent at sea by all vessels selected for that replicate.

For each set of 50 replicate estimates of annual mortality for a given fleet size, percent coverage, and dolphin group type, we calculated the average estimate ($YAVE_{50}$), the relative bias of that estimate ($RBY_{50}$), and the coefficient of variation of that estimate ($CVY_{50}$) as follows

$$YAVE_{50ijkl} = (1/50) * \sum_{m=1}^{50} YHAT_{ijklm}$$

$$RBY_{50ijkl} = 100 * (YAVE_{50ijkl} - known\ kill_{ijk})/known\ kill_{ijk}$$

and

$$CVY_{50ijkl} = [\sqrt{MSE(YAVE_{50ijkl})}/known\ kill_{ijk}]*100$$

where

$$MSE(YAVE_{50ijkl}) = \sum_{m=1}^{50}(YHAT_{ijklm} - known\ kill_{ijk})^2$$

and

$$BYAVE_{50ijkl} = YAVE_{50ijkl} - known\ kill_{ijk},$$

where $BYAVE_{50ijkl}$ is the bias of $YAVE_{50}$, and $V(YAVE_{50ijkl})$ is the variance of $YAVE_{50ijkl}$, calculated as

$$V(YAVE_{50ijkl}) = (1/49) * \sum_{m=1}^{50}(YHAT_{ijklm} - YAVE_{ijkl})^2$$

(Cochran, 1977).

The preceding equations produce 10 $YAVE_{50}$'s, 10 $RBY_{50}$'s, and 10 $CVY_{50}$'s for each combination of fleet size, percent coverage, and dolphin group type.

The average of these 10 $RBY_{50}$'s is

$$RBY_{10ijk} = (1/10) * \sum_{k=1}^{10} (RBY_{50ijkl}),$$

and the average of the 10 $CVY_{50}$'s is

$$CVY_{10ijk} = (1/10) * \sum_{k=1}^{10} CVY_{50ijkl}.$$

### Sampling distributions and confidence intervals

To facilitate interpretation of patterns seen in relative bias and coefficients of variations, we plotted both frequency distributions and analytic 95% confidence intervals for an arbitrarily selected single set of 50 individual replicate estimates of mortality derived under various combinations of conditions. The frequency distributions and confidence intervals illustrate, in particular, variations due to differences between replicates in the fleet selected, in contrast to the relative bias and coefficient of variation, which pertain to sampling properties of the estimator. Only one set of 50 replicates, of the 10 sets generated under each combination of fleet size and coverage level, is illustrated for each combination because the general messages conveyed by the figures were the same for all sets.

Frequency distributions and confidence intervals are plotted only for the cases of 5 and 20 boats at 25% and 75% coverage. Combinations of these values spanned the range of fleet sizes investigated and enabled us to examine whether problems might occur even with coverage as high as 75% when fleet size is as small as 20 (or worse, 5) boats.

The frequency distributions of the 50 estimates illustrate graphically the influence of various combinations of fleet size and observer coverage level on the behavior (dispersion) of the estimator itself (kill/day). The analytic confidence intervals for the 50 estimates illustrate the influence of various combinations of fleet size and observer coverage level, on the estimated precision that may be associated with any individual estimate.

The analytic confidence intervals for individual replicate estimates of mortality were calculated by the International Mathematical and Statistical Library (IMSL) routine SMPRR for ratio estimates (IMSL, 1987). This routine calculates confidence intervals for ratio estimates using the analytic formula for approximate variance of a ratio. The procedure is based on the assumption that a normal approximation to the ratio variance is appropriate (Cochran, 1977; IMSL, 1987). Where data are sparse (fewer than 30 data points in the data set; i.e., in most of the cases in these simulations) this assumption is generally inappropriate (e.g., Cochran, 1977), but for single replicates we had no computationally simple alternative. Bootstrapping confidence intervals for these individual replicates would have eliminated any need for a normal approximation but would have required significantly more computer time to convey essentially the same gross patterns and general message.

## Results

### Relative bias (RB)

RB was generally small overall, but exceeded the management objective of 5% for common dolphins and whitebelly spinner dolphins when coverage was low (25%; Fig. 5).

### Coefficients of variation (CV)

CV decreased with increasing percent coverage and with increasing fleet size in both the "best" data group (offshore spotted dolphin; Fig. 6) and in the "intermediate" data group (whitebelly spinner dolphin). CV decreased with increasing percent coverage but showed no consistent effect of fleet size in the "worst" data group (common dolphin).

### Sampling distributions

Frequency distributions were affected somewhat by fleet size (primarily by shifting the central tendency), noticeably by percent coverage (primarily by decreasing the spread of the distribution), and very strongly by dolphin group type (primarily in terms of the number of modes in the distributions; Figs. 7, 8, and 9). Bias and variability increased with small sample sizes and non-smooth data distributions.

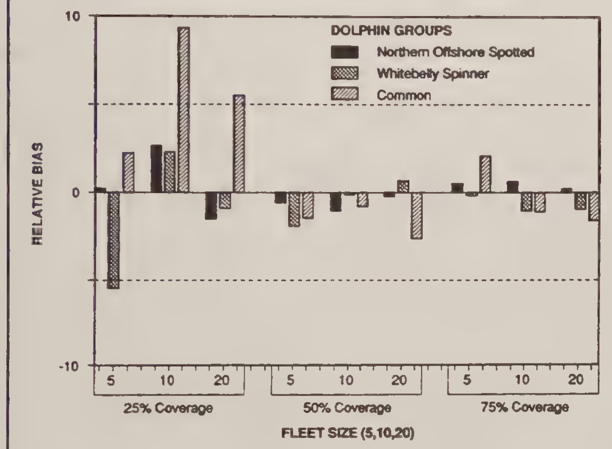

**Figure 5**

Average relative bias (%) in estimates of annual dolphin mortality as a function of fleet size and percent observer coverage. Dashed line at +5% and −5% indicates management target.

Distributions of mortality estimates for offshore spotted dolphins tended to be relatively narrow and unimodal for fleets of both 5 and 20 vessels, at high coverage (75%; Fig. 7). Distributions remained unimodel but were more dispersed, at low coverage (25%). Distributions for whitebelly spinner dolphins were also unimodal in general but tended to be more dispersed than was the case for offshore spotted dolphins (Fig. 8). Distributions for common dolphins were markedly bimodal and dispersed under all sampling conditions, reflecting the selection (or not) of the one trip with unusually high kill (Fig. 9).

Modal values of mortality estimates for all three dolphin types increased with increasing fleet size (not surprisingly, because more boats generally kill more dolphins) regardless of coverage level. Dispersion also increased with fleet size, more obviously when observer coverage was low than when coverage was high, as more data became available for analysis.

## Confidence limits

Confidence limits were affected similarly to frequency distributions. Limits were affected most strongly by dolphin group type, very noticeably by percent coverage, and less strongly but still noticeably by fleet size (Figs. 10, 11, and 12).

Mortality estimates were most stable and confidence intervals dramatically reduced for offshore spotted dolphins at high (75%) observer coverage (Fig. 10). Mortality estimates were more variable and confidence intervals wide and ragged, even with a relatively large fleet (20 boats), for offshore spotted dolphins at low observer coverage (5%). Intervals were most unstable at the combination of lowest observer coverage and smallest fleet size[4]. Confidence interval patterns for whitebelly spinner dolphins were intermediate, being more variable than patterns for northern offshore spotted dophins but being less variable than patterns for common dolphins (Fig. 11). At low coverage and small fleet size, confidence intervals for whitebelly spinner dophins showed the same bimodality characteristic of confidence intervals for common dolphins under all conditions. At high coverage, confidence intervals showed the same relatively stable and

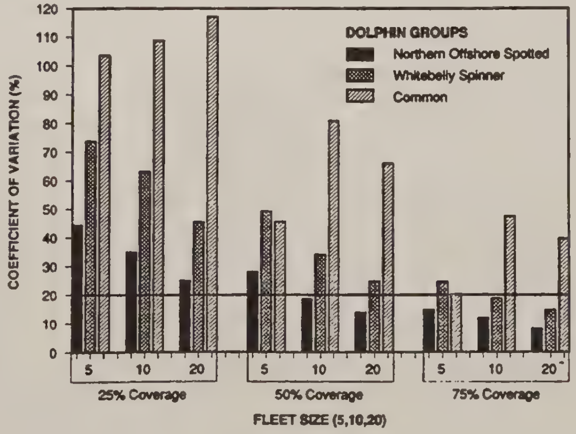

**Figure 6**

Coefficient of variation (percent) in estimates of annual dolphin mortality as a function of fleet size and percent observer coverage. Dark horizontal bar at 20% indicates management target.

---

[4] The irregular pattern of the confidence intervals observed for mortality estimates from small fleets (e.g., 5 boats) with low coverage (e.g., 5 boats, 25% coverage) are not surprising because this combination of fleet size and percent coverage means that the mortality estimates are being derived from about 4 observed trips during an entire year (assuming 5 boats make 3 trips/year, 15 trips × 0.25 = 4 trips).

narrow limits seen for offshore northern spotted dolphins at high coverage. Confidence intervals for common dolphins illustrate the problems inherent in relatively heterogeneous data, where mortality is sometimes quite high, usually relatively low, and data overall are relatively few. For this species, confidence intervals were extremely variable even with relatively high coverage (Fig. 12) and were very narrow (or nonexistent) for replicates which fortuitously included only low-kill data, but very wide for replicates including a few very high kills.

Although these analytic confidence intervals are clearly inappropriate measures for precise estimation of variance characteristics of the estimates (note negative intervals in some cases; Figs. 10, 11, and 12), they are presented here because they provide an effective illustration of the effects of varying conditions on the variability of the mortality estimates. Despite the inter-group differences, the general response to increasing coverage and increasing fleet size is similar in all three dolphin group types. Confidence intervals become narrower and more stable as more data become available.

## Discussion

### Dolphin group type

Of the three factors investigated here (dolphin group type, observer coverage level, and fleet size), dolphin group type had the greatest effect on dolphin mortality estimates, followed by percent coverage and fleet size. This hierarchy of effects is controlled by two characteristics of the kill data for each dolphin group type—*frequency* (the number of times that mortality occurs) and *variability* (differences between times in the number of dolphins killed). The *total* number killed can have relatively little influence on the quality of the estimate. This is illustrated by comparing results for whitebelly spinner dolphin and common dolphin. Although total kill was comparable for both dolphin group types (981 deaths of whitebelly spinner dolphin, 882 deaths of common dolphin; Fig. 3) the data sets differed markedly both in number of trips incurring kill (62 for whitebelly spinner dolphin, 12 for common dolphin) and in the distribution of kill per day among those trips (Fig. 3).

The data set for common dolphins exhibits the worst of both characteristics; frequency of kill was low (few trips killed common dolphins) and variability between trips in kill per day was high. These problems exemplify an unfortunate interaction between data collection problems and the ecology of the dolphins themselves. Mortality of common dolphins due to the U.S. fleet during 1987 was *infrequent* because the geographic range of this species is relatively limited and occurs primarily within Mexico's Exclusive Economic Zone. U.S. vessels rarely fish in this area, therefore common dolphins rarely die in U.S. tuna nets in this area. Mortality was *variable* at least in part because common dolphins have an unfortunate habit (in this context) of forming very large schools, pre-disposing them to the possibility of very large-kill "disaster" sets.

The data set for whitebelly spinner dolphin exhibits a problem with only one of the characteristics; data are relatively infrequent. Unlike the case for common dolphins, kill per day was not extremely variable. This similarity in kill per day generates statistics for whitebelly spinner dolphin that are much less biased and variable than for common dolphin.

### Observer coverage level

The effect of observer coverage level is influenced both by fleet size and dolphin group type. To achieve a desired level of precision and accuracy in mortality estimates, observer coverage levels will have to be higher in smaller fleets because the available data will be fewer, and higher in dolphin groups with "messy" data, because observer coverage levels affect the probability of encountering an unusually large kill[5].

Observer coverage will need to be relatively high even for large fleets, when estimating mortality of dolphins with sparse and heterogeneous data. For example, with kill data as sparse and variable as was the case for common dolphins in 1987, nearly 100% coverage would be required to generate CV's lower than 20% regardless of fleet size (Fig. 6). With more frequent and less variable kill data, such as for northern spotted dolphin in 1987, CV's lower than 20% can be achieved with 50% coverage of 10-boat fleets (Fig. 6). When fleet size drops to 5 boats, even this relatively well-behaved data set requires coverage at about 75% to achieve CV's less than about 20%. With coverage as low as 25%, even a fleet size of 20 boats was insufficient to meet the management objective of 20% CV.

### Fleet size

In smaller fleets, each data point comprises a larger fraction of the available mortality data. In particular, the influence of unusually large mortalities (e.g., the one trip responsible for over 500 deaths of common dolphins) will be much greater in smaller fleets.

---

[5] The possibility of high kills is more important than the possibility of low kills; this is because all dolphin group types experience zero kill frequently (therefore it is not unusual or unexpected). Also, zero kill is a definitive lower bound, while the upper bound on kill is limited only by the potential school size of the dolphin group.

The accuracy and precision of mortality estimates are affected less by fleet size *per se* than by observer coverage level for a given fleet size, and the fleet's variability in kill per day. Kill per day is affected not only by the fishermen's choices of fishing methods and areas, but also by the type of dolphin found associated with a given school of tuna. Because these are not factors that can be controlled, small fleets will generally require higher coverage level than larger fleets to achieve a given level of accuracy and precision in mortality estimates.

### Simulation procedures and estimates

The simulation procedure used in this study was designed to reflect the sampling process as it would occur in the real world. More precise and less biased estimates of mortality rates for the population of trips contained in the 1987 data set would have resulted from simple random sampling of the 124 trips in the data set as a whole. But simple random sampling implicitly assumes that all vessels are equal in fishing ability. This is not the case, and it is likely that some fleets as a whole may have greater (e.g., those newer to purse-seining and therefore less experienced) or lesser (e.g,, the more experienced fleets) mortality rates than the average for the ETP purse-seine fleet overall. In addition, in the real world, not all trips made by all purse-seine vessels fishing in the ETP would be available for sampling. Only trips made by the vessels in a particular fleet would be available for sampling, and only those vessels actually observed would contribute data. If vessels (or more properly, the crew) differ in their ability to release dolphins unharmed (or not), then fleets with more (or fewer) "low kill" vessels will have lower (or higher) mortality rates than other fleets of comparable size. Although it would have been possible to estimate the number of trips that would have been made, on average, by a fleet of a given size, and to have then randomly sampled that many trips from the 1987 data base, the results would have been unrealistically precise. The cluster sampling resulting from the selection of trips only after selecting vessels adds variability in the estimates but is more realistic than simple random sampling. The sampling scheme used here is a single stage cluster sampling, for which a ratio estimator is the most appropriate choice of estimation procedure (Cochran, 1977).

## Discussion

Although the kill-per-day estimator used in this simulation study is no longer used by NMFS because 100% observer coverage has made estimation unnecessary, the results of this study have general implications for current estimation procedures based on kill per set (e.g., Hall and Boyer, 1986) and for mortality estimation procedures in general where data quality may vary between stocks.

The uneven structure of the data set for common dolphins has unfortunate implications for deriving estimates of mortality for dolphin groups that are characterized by having such infrequent and widely variable kill per day. Specifically, estimates of mortality can vary widely depending on which trips happen to be chosen. In our simulation, we could resample the total population of vessels repeatedly, thus generating relatively unbiased, though individually variable, estimates of mortality. In the real world, only one sample (one set of mortality data per dolphin group type) will be collected per year. If this sample is collected under low percent coverage, it appears very likely that the data may be affected by undetectable sampling biases. This bias is more likely to underestimate than to overestimate mortality because sets with large kill are rare and likely to be underestimated, even though the mortality during such sets may be responsible for a disproportionately large percentage of the total kill.

The problem with missing the rare large-kill sets is that the kill in these sets can apparently be one or two orders of magnitude greater than the "usual" kill. For very abundant groups, missing a few large kills will miss only a small percentage of the total number of dolphins in the group; underestimating mortality could be relatively harmless. For less abundant groups, the large kills might represent a significant proportion of the existing stock. Underestimating this mortality could lead to seriously underestimating the impact of mortality due to fishing operations on these stocks.

In the case of the 1987 data set for dolphin kill by the U.S. fleet, coverage greater than 96% (the highest observed) would be required for all boats in order to generate mortality estimates for common dolphin with CV's less than 20%. Alternatively, if only the most abundant groups are considered (e.g., offshore spotted dolphin), CV's less than 20% could be achieved with only 50% coverage of fleets as small as 5 boats. There appears to be no unique solution that is optimal for all groups.

In addition, the poor quality of the data presented here for common dolphin in fact underestimates the true extent of the problem for this species. In actual practice, the species is managed as three separate stocks rather than as one combined stock as presented here. The data are thus extremely sparse for the individual stocks, and the problems with estimating mortality, given anything less than full observer coverage, are greatly exacerbated.

The results of these simulations, in particular the results for five-boat fleets, and common dolphins, strongly influenced subsequent regulations related to comparability criteria for import of tuna caught by non-U.S. fleets. These regulations now require that mortality data for common dolphins be stratified separately from all other stocks, and that non-U.S. fleets meet the U.S. requirement for 100% observer coverage[6].

Of the three factors discussed here (dolphin group type, percent coverage, and fleet size), only percent coverage can be controlled by the sampling program. Our results imply that providing maximum protection for all dolphin groups would require mandating coverage to achieve a desired level of statistical precision for the dolphin group type with the least statistically stable data.

## Acknowledgments

The U.S. fleet simulation study was designed by Bruce Wahlen. Nancy Lo and Peter Perkins provided insightful advice about sampling procedures and statistical methods. We thank also the participants in the Workshop on Estimating Dolphin Mortality, and two anonymous reviewers, who provided many useful comments during the review process.

## Abstract

Of the shearwaters that breed in the North Pacific, the species in the most peril at present is Townsend's Shearwater *Puffinus auricularis*. Feral cats and pigs pose a threat on its breeding grounds. More information is needed on its current status, and that of the Black-vented Shearwater *P. opisthomelas*, most of whose nesting colonies have well-established feral cat populations. Efforts are being made to protect Newell's Shearwater *P. newelli* in the Hawaiian Islands. The single greatest threat to migrant shearwaters in the North Pacific is drift gillnet fisheries, which kill hundreds of thousands of birds annually.

## Résumé

De tous les puffins qui se reproduisent dans le Pacifique Nord, le Puffin de Townsend *Puffinus auricularis* est l'espèce la plus menacée. Les chats et les porcs retournés à l'état sauvage détruisent ses lieux de nidification. Il faut recueillir davantage d'information sur sa situation actuelle et sur celle du Puffin cul-noir *P. opisthomelas*, dont la plupart des colonies comptent également des populations bien établies de chats féraux. On s'efforce actuellement de protéger le Puffin de Newell *P. newelli* dans les îles Hawaï. La pêche au filet maillant dérivant provoque la mort de centaines de milliers d'oiseaux chaque année et constitue la plus grande menace pour les puffins migrateurs qui séjournent dans les eaux du Pacifique Nord.

## 1. Introduction

Eleven species of shearwaters (*Calonectris leucomelas* and 10 *Puffinus* species) regularly occur in the North Pacific Ocean, north of the equator. Of these, six species breed on islands north of the equator, and the other five are trans-equatorial migrants that breed in the southern hemisphere during the austral summer. Audubon's Shearwater *P. lherminieri*, a tropical species with a small fringe population breeding on the Bonin Islands, Japan (slightly north of the Tropic of Cancer), will not be considered here.

Despite their relative abundance, little is known about the biology of shearwaters in the North Pacific. Most of the published information on life histories is anecdotal and often many decades old. Remote, rugged, and inaccessible islands are the preferred breeding locales for many species. Consequently, population estimates, where available, are frequently based only on educated guesses. Within the last 20 years, however, the level of effort expended on pelagic studies of many seabirds, including shearwaters, has increased dramatically, yielding many new facts on behaviour, habitat selection, migratory routes and timing, feeding habits, and mortality.

In this paper we discuss the general biology and status of each of the shearwater species occurring in the North Pacific, consider threats and hazards both on land and at sea, and offer recommendations for future study and conservation efforts.

## 2. Species accounts

### 2.1. *Calonectris leucomelas* Streaked Shearwater

This species breeds in the far-western Pacific at many locations from the Ryukyu and Bonin islands north to Qingdao Island in the Yellow Sea, islands off northern Honshu, Japan (Melville 1984; Hasegawa 1984), and has nested on Karamizin Island in the former U.S.S.R. (Litvinenko 1976). Details on its breeding biology at Soviet and Japanese colonies are provided by Yoshida (1962, 1981), Okamoto (1972), Litvinenko (1976), and Tan (1977). The breeding season extends from February to November, and most eggs are laid in May and June. The birds nest in large, dense colonies in forested areas. After breeding, the birds disperse south to the East and South China seas, the Philippine Sea, and as far south as Borneo and New Guinea (Shuntov 1972). A few are regularly seen in winter off the north and east coasts of Australia (Blakers et al. 1984; Marchant and Higgens 1990).

Streaked Shearwaters are abundant within their range. The total population is perhaps 4–5 million individuals. Although there is no apparent cause for concern for the overall well-being of the species, "large numbers" of birds have been incidentally caught in fishing nets off Taiwan (Blackshaw 1978) and near Hong Kong (Melville 1984). Eggs and chicks have been sold in markets in Taipei (Blackshaw 1978) and Hong Kong (D.S. Melville, pers. commun.). We found no information on mortality in Japanese nearshore gillnet fisheries, but some incidental take is likely. Mass accidental deaths have taken place in anchovy crawls off Honshu, Japan (Nakamura 1974). Increased habitation of remote breeding islands by transient fishermen (Okamoto 1982) present potential threats warranting increased vigilance.

### 2.2. *Puffinus creatopus* Pink-footed Shearwater

This trans-equatorial migratory species breeds on Masatierra and Santa Clara islands in the Juan Fernandez group, Isla Mocha, and possibly a few other islands off southern Chile (Johnson 1965). What little is known about its breeding biology comes primarily from the notes of R.H. Beck (Bent 1922;

Murphy 1936) and D.S. Bullock (Murphy 1936; Johnson 1965). Birds return to the colonies in November and December, with egg-laying commencing in December and January. Fledging and departure from the islands apparently begin in March and April.

Birds disperse as far north as the Gulf of Alaska and southern Bering Sea (American Ornithologists' Union 1983). However, Vermeer et al. (1987) suggest that the west coast of British Columbia represents the northern limit of where they regularly occur. The species is essentially restricted to the eastern Pacific (Harrison 1983; Pitman 1986). Peak numbers occur in the North Pacific from July to October.

There are no population estimates, but the species is said to occur in "large numbers" on the breeding grounds (Schlatter 1984), and is certainly fairly common in migration. On the Juan Fernandez Islands the species is reportedly declining due to the destructive activities of coatimundis *Nasua narica*, feral cats, rabbits, and goats. No significant fishery-related mortality has been reported for Pink-footed Shearwaters.

### 2.3. *Puffinus carneipes* Flesh-footed Shearwater

Breeding colonies are found on islands off the south coast of western Australia, on Lord Howe Island (van Tets and Fullagar 1984), and on islands off the coast of New Zealand's North Island (Robertson and Bell 1984). In addition, 20–30 pairs breed on Saint Paul Island in the south-central Indian Ocean (Segonzac 1970).

Information on the biology of the species is provided by Warham (1958) and Serventy et al. (1971). Birds return to the colonies in late September, eggs are laid in November and December, and fledging occurs in April and May. This species is also a trans-equatorial migrant, with most of the population believed to winter in the western Pacific Ocean or Indian Ocean. The migratory route is poorly known, but some birds move along the west coast of the Americas (Murphy 1936; American Ornithologists' Union 1983; Pitman 1986). The size of the western Australia population is unknown but is estimated to be greater than 650 000 birds occupying at least 33 islands (Blakers et al. 1984). Another 20 000–40 000 pairs breed on Lord Howe Island (Fullagar and Disney 1981). The New Zealand colonies contain 50 000–100 000 pairs (Robertson and Bell 1984).

There is some concern over the destruction of lowland forests on Lord Howe Island, and the resultant reduction of breeding habitat (Robertson and Bell 1984). Introduced predators are also a problem on some islands, but some remedial efforts are under way (van Tets and Fullagar 1984). This species is a deep diver (Murphy 1936; Serventy et al. 1971) and as such is more vulnerable to fishing operations (Robertson and Bell 1984). In addition, some birds may still be taken from burrows for food. At present, none of these factors seems to present a serious or substantial threat to the species.

### 2.4. *Puffinus pacificus* Wedge-tailed Shearwater

This species is by far the most abundant and widespread breeding shearwater in the tropical Pacific and Indian oceans (Marchant and Higgens 1990; Warham 1990). Specific colony locations include Isla San Benedicto in Los Islas Revillagigedo, Mexico (at most a few thousand pairs; Pitman, unpubl. data), the Hawaiian Islands (ca. 575 000 pairs; Fefer et al. 1984; Harrison et al. 1984), Johnston Atoll (3000 birds; Amerson and Shelton 1976), Christmas Island (6000 birds; King 1974), Phoenix Islands (10 000 birds; King 1974), Taongi, Marshall Islands (12 000+ birds; King 1974), the Bonin Islands, Iwo and Marcus islands, Japan (breeds in "large numbers"; Hasegawa 1984). In Australia it breeds at numerous sites along both the west and east coasts, especially in the areas of Queensland and New South Wales (see van Tets and Fullagar 1984), with major colonies at North West Island (724 560 birds; Domm and Messersmith 1990), Heron Island (16 000 birds; Ogden 1979), Masthead Island (10 000+ birds; Jahnke 1977), Norfolk Island ("several hundred thousand birds"; Tarburton 1981), and Lord Howe Island (60 000; Fullagar et al. 1974). Other known breeding locations without estimates of numbers include Pitcairn, Gambier, Marquesas, Australs, Tonga and Niue, Fiji, and New Caledonia (see Garnett 1984). Wedge-tailed Shearwaters are also present on Jarvis and Howland islands in small numbers (Kirkpatrick and Rauzon 1986).

Breeding occurs mainly on low islands, where the species is primarily a burrow nester. Northern subtropical populations breed from April to November and southern subtropical populations breed from October to May (King 1974). Little is known about migratory movements. Rogers (1975) showed that birds departed waters off southeast Australia during the austral winter and returned in the spring to breed. Many banded birds from this population have been recovered in the Philippines, indicating that some individuals migrate to other areas. Pitman (1986) recorded large numbers of white morph Wedge-tailed Shearwaters in the far-eastern Pacific that presumably originated from central Pacific colonies. The only colony in the eastern Pacific (San Benedicto Island, see above) is small and comprises predominantly dark morphs (Jehl and Parkes 1982).

Wedge-tailed Shearwaters occupy relatively productive tropical waters, where they are often dominant in mixed-species flocks associated with foraging tunas and dolphins (Murphy and Ikehara 1955; King 1970; Au and Pitman 1986).

Although Wedge-tailed Shearwaters continue to be widespread and abundant in the tropics, it is likely that gillnet fisheries will result in some mortality. There have been some localized threats to individual breeding colonies where habitats have been altered or predators introduced (e.g., Johnston Atoll, Amerson and Shelton 1976; Jarvis Island, Rauzon 1985; Howland Island, Kirkpatrick and Rauzon 1986; Midway Island, Woodby 1988; Mariana Islands, Reichel 1991). Studies at Heron Island, Australia (Hill and Rosier 1989), suggest that well-managed development can, in some cases, be compatible with breeding colonies. However, it seems unlikely that rats can be kept off human-occupied islands indefinitely.

### 2.5. *Puffinus bulleri* Buller's (New Zealand) Shearwater

This subtropical, trans-equatorial migratory species is known to breed only on the Poor Knights Islands, off North Island, New Zealand. The total population is estimated at 2.5 million birds (Harper 1983). According to Harper (1983), birds arrive at the nesting islands in mid-September, refurbish burrows, and then leave for a 30-day pre-laying "honeymoon" at the end of October. They return to lay eggs at the end of November. The egg is incubated for approximately 51 days. Hatching occurs in mid-January and most fledglings leave the islands in early May. The majority of nests are in excavated burrows or in caverns under rocks.

By June, most of the birds have left New Zealand waters and travelled north to summer in the North Pacific (Jenkins 1988). Northward migration appears to be mainly through the western Pacific, as only small numbers have been observed migrating through the tropics in the central Pacific (Gould 1971; Cheshire 1974; Jenkins 1986). Only stragglers occur in the eastern Pacific (Pitman 1986). Migrants travel quickly through the tropics, but will temporarily join feeding flocks they encounter along the way (Gould 1971; Pitman, unpubl. data).

Significant numbers of Buller's Shearwaters arrive in the North Pacific in June. During July and August they move increasingly northwards and eastwards as far as the Gulf of Alaska (Wahl 1985). By September most of the breeding birds have once again departed for New Zealand. A large build-up off the North American west coast during September and October probably comprises mainly lingering prebreeders taking advantage of abundant food resources (Wahl 1985; Briggs et al. 1987). By November most of these have moved south also, and only occasional stragglers are reported in the North Pacific during the winter.

Buller's Shearwaters have increased dramatically since the turn of the century after introduced pigs were eliminated from one of the major nesting colonies. Harper (1983) stated that the population at Aorangi Island increased from 100 pairs in 1938 to about 200 000 pairs in 1981. This increase is apparently responsible for a widening distribution reported in recent years in New Zealand waters (Jenkins 1988) and the North Pacific (Guzman and Myres 1983; Wahl 1985). Being less inclined to dive makes this species less vulnerable to gillnet entanglement than other species of shearwaters.

### 2.6. *Puffinus griseus* Sooty Shearwater

This species breeds in large numbers on both sides of the South Pacific, with large colonies on islands around New Zealand and off southern Chile. South American colonies in the Pacific include Chiloe Island (Marin 1984), Guafo Island (min. 200 000 birds; Clark et al. 1984a), Guamblin Island (Clark et al. 1984b), and islands around Cape Horn (Murphy 1936; Johnson 1965). New Zealand hosts numerous large colonies (Robertson and Bell 1984), including the immense Snares Islands population (2 750 000 pairs; Warham and Wilson 1982). Nesting also occurs on Macquarie Island (1770 pairs; Brothers 1984). Relatively small numbers breed off Australia (Lane and White 1983), the largest colony being 1000 pairs on Tasman Island, Tasmania (Brothers 1979).

The following phenology is from Warham et al. (1982) and pertains to breeding in New Zealand, but, as pointed out by the authors, appears to apply with slight differences to all the known populations. Birds arrive at the colony in early September and eggs are laid in mid-November. After an incubation period of 53 days, chicks hatch in mid-January. Adults raise the chicks until the third week of April and then depart. Most of the chicks depart between the last week of April and the first week in May.

At the end of the breeding season birds migrate to northern oceans for the boreal summer. The majority of birds that migrate to the North Pacific seem to make a clockwise circumnavigation, moving north past Japan in the spring, crossing south of the Aleutian Islands in summer, and then proceeding south along the west coast of the Americas during the fall (Murphy 1936). However, much still remains to be learned about this species' movement patterns (Briggs and Chu 1986). For example, flocks containing as many as 90 000 birds have been observed along the west coast of British Columbia in early May (Vermeer and Rankin 1984a).

There seems to be no immediate serious threat to birds at breeding colonies in New Zealand. Efforts are being made to eliminate introduced predators from many of the important seabird islands (Robertson and Bell 1984; Veitch 1985). Considerably less is known, however, about the status, or even distribution, of colonies off southern Chile.

The major hazard for birds at sea in the North Pacific at this writing is probably incidental take by gillnet fishing. Relatively few Sooty Shearwaters were killed by drift gill nets in the high-seas Japanese salmon mothership fishery during 1981–1984, presumably because the fishery operated north of the main migratory route for this species (Jones and DeGange 1988). DeGange et al. (1985) estimated that Sooty Shearwaters constituted only 0.3% of the total incidental bird kill in that fishery between 1981 and 1984. However, the preliminary information on the North Pacific drift gillnet fishery for squid, which operates at a lower latitude, suggests Sooty Shearwaters may currently sustain losses of up to 400 000 individuals annually (Gjernes et al. 1990). There is also very little specific information available on incidental shearwater mortality in gillnet fisheries off California (Herrick and Hanan 1988), where the species numbers in the millions at times and is often the most abundant seabird species present during the summer months (Briggs et al. 1987). A cooperative observer program operated by the National Marine Fisheries Service and California Department of Fish and Game began in spring 1990, and observers placed on gillnet boats have been collecting data on seabird mortality during fishing operations.

### 2.7. *Puffinus tenuirostris* Short-tailed Shearwater

The Short-tailed Shearwater breeds only in Tasmania and on islands off southeast Australia. Skira et al. (1985, and references therein) estimated 11.4 million burrows from 167 colonies in Tasmania, 1.45 million burrows in Victoria, 1.5 ± 0.5 million burrows in South Australia, 25 700 breeding pairs in New South Wales, and 250 burrows in Western Australia. The total world population is roughly 23 million birds.

According to Serventy (1967), birds first arrive on the breeding islands the last week in September and for the next four weeks they prepare their burrows. After a two-week pre-laying exodus, most egg-laying occurs in the last week of November. Males and females share incubation duties in shifts of 10–16 days. The single egg hatches in about 53 days and the chicks depart from mid-April to the first week in May, after spending about 94 days in the burrow (Skira et al. 1985).

The trans-equatorial migration of this species apparently takes it north through the far-western Pacific past Japan to its main wintering (austral) grounds off the Aleutian Islands and in the Bering Sea. The return migration, in August and September, is thought to take place primarily through the central Pacific (Lindsey 1986; Pitman 1986; Warham 1990).

Populations at managed breeding colonies appear stable despite the annual combined commercial and noncommercial harvest of an estimated 700 000 chicks (Skira et al. 1985; Skira 1987). Substantial numbers of Short-tailed Shearwaters perish each year in high-seas drift gillnet fisheries in the North Pacific Ocean (King 1984; DeGange et al. 1985; Atkins and Heneman 1987; Jones and DeGange 1988; Gjernes et al. 1990). The incidental kill is in the hundreds of thousands of birds annually, and undoubtedly millions have perished since the fisheries began. Although the species is apparently still abundant, the combined effects of incidental kill, harvesting, and natural mortality could eventually decimate and jeopardize the species.

### 2.8. *Puffinus nativitatis* Christmas (Island) Shearwater

Confined to the Pacific Ocean, this little-known species breeds at Easter Island (Johnson et al. 1970), Oeno, Ducie, and likely Henderson islands, the Pitcairn group (Williams 1960; Schubel and Steadman 1989), Gambier (Thibault 1973), the Tuamotus and Austral group (Holyoak 1973), Taongi Atoll in the Marshall Islands (Amerson 1969), the Marquesas (King 1967), Johnston Atoll, and the Hawaiian Islands (Harrison et al. 1984); it apparently formerly bred on Wake, Marcus, and the Bonin islands (King 1967).

Information on population sizes is scant. Ashmole and Ashmole (1967) reported the Christmas Island population to be 7000 birds, making it the largest known colony. Harrison and Jehl (1988) estimated 2500 pairs nesting at Sala y Gomez, Chile. Fefer et al. (1984) reported a total of 2960 pairs nesting in the northwest Hawaiian Islands, and Amerson and Shelton (1976) estimated 30 individuals on Johnston Atoll. The Easter Island population consisted of 80–100 pairs in 1968 (Johnson et al. 1970). Comprehensive accurate data are lacking, but a world population on the order of a few tens of thousands seems likely.

Breeding is year-round on equatorial Christmas Island (Schreiber and Ashmole 1970), but seasonal in the more subtropical Hawaiian Islands, where adults return to colonies in March and fledge most of their young by late September (Richardson 1957; Fefer et al. 1984). Nesting usually occurs in fairly open areas, in rock crevices or under vegetation (Shallenberger 1984). Unlike most other species of *Puffinus*, Christmas Shearwaters do not nest in burrows.

Open ocean waters are preferred by this species, and it is uncommon but regular throughout the eastern and central tropical Pacific (King 1967; Pitman 1986). Although there is no published information to suggest that populations undergo any regular migrations within the tropics, moderate numbers are usually present off the coasts of central and southern Mexico and Central America (Pitman, unpubl. data), more than 4500 km from the nearest known nesting colony, suggesting regular movements to that area.

There appear to be no major threats to this species at sea. Breeding colonies in Hawaii were adversely affected by introduced rabbits, but seemed to recover when the rabbits were eliminated (Harrison et al. 1984). The Johnston Atoll population declined from 400 to 30 birds after the island was occupied by the military and a paved airstrip was installed (Amerson and Shelton 1976). There is concern for the small Midway Island population (25–50 pairs; Fefer et al. 1984), which is currently threatened by introduced black rats *Rattus rattus* (Woodby 1988).

### 2.9. *Puffinus opisthomelas* Black-vented Shearwater

The only documented breeding locales of this species are at Isla Guadalupe, Isla Natividad, and Islas San Benito, all off the west coast of Baja California, Mexico (Everett 1988a). On Isla Natividad, the shearwaters burrow in the sandy soil covering most of the southeast portion of the island. The only known active colonies at Isla Guadalupe are on two offshore islets, Isolote Negro and Isolote Afuera. Anthony (1900) reported breeding on the main island of Guadalupe, but exact locations have never been determined. The introduction of cats to the island may have resulted in abandonment of these breeding grounds. At Islas San Benito, nests have been found on all three islands, but nowhere in any large concentration. At both Guadalupe and the San Benitos, birds occupy natural holes in the lava or crevices, or they burrow under large boulders.

Based on the limited available information, breeding colonies are occupied by mid-January and the peak of laying is in early April. By June many burrows have a chick, and fledging occurs from late June through August (Everett 1988a).

Black-vented Shearwaters primarily inhabit coastal waters, up to 25 km offshore. During the breeding season they are uncommon in areas other than the Pacific coast of Baja California. When breeding is concluded many disperse to the north and south. Typically, birds that head north move into the Southern California Bight, from Point Conception to Islas Los Coronados. During some years they are found as far north as Monterey Bay. Stragglers have been recorded as far north as British Columbia (Campbell et al. 1990). South of Cabo San Lucas there are few data, and the situation is complicated because of the occurrence of mixed flocks of *P. opisthomelas/auricularis* (Jehl 1974, 1982).

The estimate of population size is speculative, based primarily on observations and counts of birds staging at dusk near the breeding islands. The number of pairs is likely in the following range: Isla Guadalupe 500–2500, Islas San Benito 250–500, Isla Natividad 2500–5000. Feral cats are established on most of the breeding islands, and all visitors to these colonies have reported widespread destruction. Huge flocks such as those reported at the turn of the century (Anthony 1896; Grinnell 1897) are no longer seen. Gillnet fisheries have expanded off the west coast of Baja California in recent years, but the impact of these operations (Atkins and Heneman 1987) on the Black-vented Shearwater population is completely unknown.

### 2.10. *Puffinus auricularis* Townsend's Shearwater

Isla Socorro and Isla Clarion in Las Islas Revillagigedo, off the west coast of Mexico, are the only known recent nesting locales for this species, which also formerly bred on Isla San Benedicto in the same group (Jehl 1982; Everett and Anderson 1991). Jehl (1982) most recently summarized the scant available information on the biology of this endangered species. The birds apparently return to the islands beginning in mid-November. Laying probably begins in January, as large young have been found in late April.

The pelagic range of this species is among the smallest of any seabird, extending in a narrow band of subtropical water between 11 and 23°N, from the Mexican mainland to about 400 nautical miles southwest of Isla Clarion (Pitman 1986).

There has been no census on either breeding island, but Jehl estimated 1000 pairs on Isla Socorro in 1981. The population on Isla Clarion in 1986 was thought to be at best slightly less (Everett, unpubl. data). A massive volcanic eruption in 1952 eliminated the colony on Isla San Benedicto, and the other breeding islands are suffering the effects of introduced predators and herbivores. Pigs and rabbits were introduced to Clarion in 1979 (Everett 1988b), and feral cats have long been observed on Socorro (which is much larger than Clarion) from sea level to the summit of this rugged volcanic island. All visitors (including Pitman in 1988) report mass destruction of shearwaters, feathers in scat, and similar signs of decline. A visit to Clarion in May 1990 (Santaella and Sada, in press) raised the disturbing possibility that the species has now been extirpated from the island.

There is a modest program under way to rid Socorro of cats, but this will be a difficult and perhaps impossible task given the large size of the island and the mostly hostile terrain (see Veitch 1985). Preserving the species on Clarion may be more feasible, if remedial steps are undertaken soon (see recommendations below). Based on observations in May 1990 of birds flying inland at dusk (Santaella and Sada, in press), it is possible the species may be recolonizing Isla San Benedicto.

2.11. *Puffinus newelli* Newell's Shearwater

Once common on several of the Hawaiian Islands, Newell's Shearwater is now known to breed only on the island of Kauai. Recent observations suggest that small colonies may still exist on other main Hawaiian Islands (Harrison 1990). Although the species was thought to be extinct for many years, a documented record was obtained in 1954 (Richardson 1955), and by 1967 the nesting grounds were rediscovered (Sincock and Swedberg 1969). King and Gould (1967) summarized historic information on the biology of the species. The breeding season extends from April to November (Harrison 1990), after which at least some of the population disperses to the north and southeast (Pitman 1986).

The most recent population estimate suggests that up to 6000 pairs inhabit Kauai (Harrison et al. 1984). The species' decline has been blamed on predation by pigs, cats, mongooses, rats, and Barn Owls *Tyto alba*. Fire has also destroyed some colonies. Another significant problem has been coastal street lights, which attract and disorient fledglings on their first flights to the ocean. The problem, most serious on moonless nights, has been somewhat mitigated by shielding upward radiation of light and by an intense salvage program to find and return stranded birds to the sea. Over 20 000 birds have been assisted in this manner (Reed et al. 1985; Tefler et al. 1987; Reed 1987; Harrison 1990).

In addition, cross-fostering with Wedge-tailed Shearwaters has been attempted in order to encourage establishment of new colonies on offshore islets free from terrestrial predation and light distraction (Byrd et al. 1984). Results of this experiment, in terms of birds returning to the foster colonies to breed, are as yet unavailable.

## 3. Hazards for shearwaters at sea

At present, the most serious threat to shearwaters at sea is undoubtedly incidental mortality in drift gillnet fisheries (King 1984; DeGange et al. 1985; Atkins and Heneman 1987). The species suffering the greatest losses is apparently the Short-tailed Shearwater, whose high-latitude migration places it in regions heavily fished (Jones and DeGange 1988). Its pursuit-diving habits also enhance its susceptibility to entanglement. Other diving species (e.g., Wedge-tailed and Christmas shearwaters) are not as gregarious or occur in areas of lower fishing effort. Although the Japanese high-seas salmon driftnet fishery has recently reduced its kill, concern is escalating regarding the incidental take in the North Pacific squid *Ommastrephes bartrami* fishery (King 1984). Preliminary results from a pilot observer program in this fishery are alarming, suggesting mortality in the hundreds of thousands for Sooty and Short-tailed shearwaters (Gjernes et al. 1990). At this writing, an expanded observer program is under way, and a call for a ban on all drift gillnet fishing has been made by the United Nations. The Japanese have agreed to cease their driftnet fisheries, but other nations such as Korea and Taiwan have yet to comply. Although the numbers of shearwaters killed in fishery operations have been massive, there is no current evidence of population declines for the species involved. However, shearwaters are notoriously difficult to census, so the situation heightens the need for monitoring breeding colonies.

Although competition with commercial fisheries may present problems for other groups of seabirds (Furness and Ainley 1984; Furness and Monaghan 1987), we know of no serious prey depletions adversely affecting shearwaters.

Oil spills also clearly present a threat to shearwaters, especially those inhabiting regions where shipping or extraction activities are high. After the *Exxon Valdez* spill in Alaskan waters in March 1989, many thousands of dead shearwaters were recovered, although the number of mortalities directly related to the spill is not clearly known (Piatt et al. 1990).

Ingestion of plastics at sea is a concern for many species of seabirds (Furness and Monaghan 1987), with both northern and southern hemisphere procellariiforms being heavily contaminated. The primary difficulty with plastics ingestion seems to be a reduction of gizzard and stomach capacity, with possible resultant malnutrition or starvation (Conners and Smith 1982; Ryan 1988). This has not, however, been demonstrated in shearwaters, which apparently have the ability to regurgitate undigestible items (e.g., squid beaks). At this time, plastic ingestion does not appear to be a significant problem for shearwaters.

## 4. Hazards for shearwaters on land

Many seabirds, including shearwaters, encounter problems resulting from habitat destruction and disturbance when they return to land to breed (Vermeer and Rankin 1984b). This can result directly from human activities or be a consequence of the introduction of alien animals. For species under consideration here, direct human disturbance has apparently been a factor in the declines of several tropical colonies. Occupation of remote islands by the military, especially where airstrips have been installed, has proven destructive to shearwaters (King 1973; Amerson and Shelton 1976; Rauzon 1985). Light attraction, discussed above, is a serious problem for Newell's Shearwater. Remedial action seems to be helping, and, fortunately, this problem is unlikely to affect most other shearwater species. The introduction of pigs and rabbits to Isla Clarion (Everett 1988b) has dramatically altered the island's landscape. The soil destabilization and erosion caused by their activities may destroy the breeding grounds of Townsend's Shearwater.

The most serious problem facing shearwaters on land is predation by introduced animals. The general impacts are well documented (Moors and Atkinson 1984), and need not be reiterated here. Species at the highest risk are those with small populations and few colonies. In addition, shearwaters breeding on high, thickly vegetated islands stand a more substantial likelihood of depredation because predators are more likely to become established in lush areas with alternative food sources available when shearwaters are absent. Many of the species discussed here suffer from predation, but Townsend's Shearwater, Newell's Shearwater, and possibly Black-vented Shearwater seem to be experiencing serious population declines as a result.

## 5. Recommendations

(1) Immediate action is required to rid Isla Clarion of pigs, then rabbits, in order to secure the island as a breeding locale for Townsend's Shearwater. Efforts are under way to remove feral cats from Isla Socorro, but that island is large and the terrain extremely difficult. Considering these problems it appears unlikely that the cat eradication program there will be successful in the near future.

(2) All drift gillnet fisheries should be banned or closely monitored and regulated. In cases where large numbers of shearwaters are being killed, fishing moratoriums should be implemented until it can be determined that serious seabird population declines are not resulting. This cannot be accomplished without careful censuses at breeding colonies over a period of several years at minimum.

(3) The population status and vulnerability of Black-vented Shearwater colonies should be determined, with implementation of appropriate remedial actions and policies if necessary.

(4) The multi-faceted program to protect and preserve Newell's Shearwater in Hawaii should be continued, including increased efforts to locate additional colonies.

(5) Predator removal programs currently in progress in New Zealand, Australia, and the central Pacific should be continued as long as required to achieve eradication.

### Acknowledgements

D. Melville kindly provided much information on shearwaters of the western Pacific. P. Gould contributed unpublished data on gillnet fisheries. J. Warham, I. Skira, K. Morgan, and E. Chu reviewed and improved early drafts of the manuscript.

# Preliminary Winter Abundance Estimates for Cetaceans Along the California Coast Based on a 1991 Aerial Survey

Karin A. Forney and Jay Barlow

*Southwest Fisheries Science Center, PO Box 271, La Jolla, CA 92038, USA*

## ABSTRACT

We present the results of an aerial line transect census of cetaceans along the California coast during March and April 1991. This survey was the first of two aerial surveys designed to estimate cetacean abundance within approximately 100–150 n.miles (185–278km) of the coast. A primary team of two observers searched through bubble windows which allowed an unobstructed view of the trackline directly underneath the aircraft. A third, semi-independent observer searched through a belly window and made observations of animals that were missed by the primary team. A total of 155 sightings were made of a minimum of 14 cetacean species (some animals could only be identified to higher taxa). Of those groups that were on the trackline, the fraction seen by at least one team, $g(0)$, was estimated to be at least 0.821 for groups of $\leq$10 small cetaceans, 0.956 for groups of >10 small cetaceans and 0.977 for medium and large cetaceans. Estimates of abundance using these correction factors are 277,783 common dolphins (CV=0.46), 10,506 Risso's dolphins (CV=0.48), 46,334 Pacific white-sided dolphins (CV=0.78), 13,362 northern right whale dolphins (CV=0.41), 1,236 harbor porpoise (CV=0.45), 5,832 Dall's porpoise (CV=0.28), 4,011 bottlenose dolphins (CV=0.62), 117 minke whales (CV=0.68), 1,720 gray whales (CV=0.42), 405 humpback whales (CV=0.42), 87 killer whales (CV=0.76), 56 sperm whales (CV=1.07), 505 beaked whales (CV=0.44) and 59 fin/sei/Bryde's whales (CV=1.00).

KEYWORDS: SURVEY-AERIAL; NORTH ATLANTIC; ASSESSMENT; COMMON DOLPHIN; RISSO'S DOLPHIN; WHITE-SIDED DOLPHIN; RIGHT WHALE DOLPHIN; HARBOUR PORPOISE; DALL'S PORPOISE; BOTTLENOSE DOLPHIN; MINKE WHALE; GRAY WHALE; HUMPBACK WHALE; KILLER WHALE; SPERM WHALE; BEAKED WHALE; FIN WHALE; SEI WHALE; BRYDE'S WHALE.

## INTRODUCTION

Under the 1988 Amendment to the US Marine Mammal Protection Act, incidental mortality of marine mammals in commercial fishing operations was authorised for the five-year period 1988–93. During this period, additional data had to be collected on the affected marine mammal species in order to provide a basis for future management decisions. Recent estimates of incidental marine mammal mortality in US west coast gillnet fisheries have been obtained through the National Marine Fisheries Service (NMFS) observer program, which began in 1990 (Perkins *et al.*, 1992; Lennert *et al.*, 1993); however, recent estimates of cetacean abundance in the fishery area are lacking. For many of the common species of cetaceans in California, the only available population estimates are over 10 years old (Dohl *et al.*, 1978; 1983) and statistical confidence limits are available only for common dolphins, *Delphinus delphis* (Dohl *et al.*, 1986). For future management considerations, new abundance estimates, including statistical confidence limits, are necessary.

In 1991 and 1992, NMFS conducted a series of two aerial surveys (March-April 1991 and February-April 1992) and one ship survey (August-November 1991) along the California coast. Standard line transect methods were used from both platforms, and the surveys were designed to yield a target level of precision (coefficient of variation (CV) < 36%) in the abundance estimates of the most common species. Due to the pronounced seasonality in the California Current, and evidence of seasonality in the abundance of common dolphins (Dohl *et al.*, 1986), separate abundance estimates were deemed appropriate for winter (cold water) and summer (warm water) conditions. The survey periods were chosen based on climatic atlases of the California coast which show that, on average, March/April have the coldest sea surface temperatures, and September/October the warmest.

This paper presents the results of the 1991 aerial survey. Although the results are preliminary (the survey design indicated that two aerial surveys would be required to obtain an acceptable level of precision) we believe it is important to present them at this time given the lack of recent estimates for the majority of cetacean species in California. Final results will be presented for the two combined aerial surveys and for the ship survey when all data have been compiled and analysed.

## SURVEY METHODS

### Study area

The study area (Fig. 1) extends beyond the continental shelf edge along the California coast, to roughly the 3,000–4,000m depth isobath. This study area was defined on the basis of fisheries that are known to take marine mammals; the boundaries do not reflect the distributional boundaries of any known marine mammal populations. It encompasses all of the known coastal gillnet fishing area, based on effort data from the California Department of Fish and Game (CDFG). In central and northern California, this extends from the coast to approximately 100 n.miles (185km) perpendicular distance offshore. In the Southern California Bight, the study area is bounded by the US/Mexico border in the South and extends out to approximately 150 n.miles (278km) offshore. It then follows a straight line northwestward to a point 100 n.miles (185km) off Point Conception, connecting with the outer boundary of the central California area (see Fig. 1).

### Transects

A total of 154 transects form two approximately uniform, overlapping grids with lines spaced roughly 45–50 n.miles (83–93km) apart. This yields an overall grid with lines spaced approximately 22–25 n.miles (41-46km) apart (Fig. 1). The location of the grid was chosen without reference to

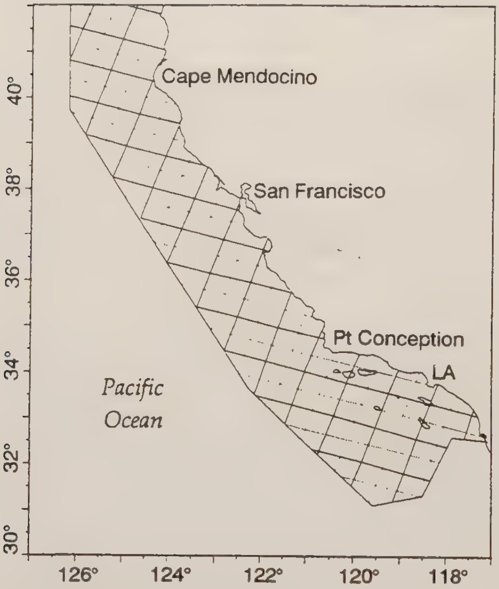

Fig. 1. Study area with two overlapping transects grids. The solid line represents Grid 1, the dotted line Grid 2.

specific areas or topographical features. They are oriented to reduce sun glare during the surveys while providing approximately uniform coverage of the study area and minimising non-survey travel time. Survey direction along transects was chosen to minimise glare, generally in a northeast or northwest direction. To avoid potential differences in regional coverage, an attempt was made to complete all transects of the first grid, providing coarse coverage of the entire study area, before beginning the second grid.

### Equipment and procedures

The survey platform was a twin-engine turbo-prop *DeHavilland* Twin Otter, with capacity for five scientists and two pilots. Surveys were conducted at approximately 700ft (213m) altitude and 100 knots (167–185km/hr) airspeed. The surveys were designed to obtain abundance estimates for cetaceans, but pinnipeds were recorded when seen farther than 10km from land to provide information on their offshore distribution. Turtle sightings were also recorded. Two 'primary' observers searched through bubble windows on the left and right sides of the aircraft. These windows allowed viewing to the side and directly beneath the aircraft with at least 10° of overlap between sides. To achieve higher sighting efficiency near the trackline, observers searched for cetaceans only out to 1,000m perpendicular distance (12° declination angle).

A round 18in (46cm) viewing hole in the belly of the aircraft was used for monitoring of the trackline by a 'secondary' observer. This viewing port provided visibility of the trackline between 55° left and 55° right declination, overlapping considerably with the primary observers. The secondary observer reported cetaceans missed by the primary team, so that the fraction of animals missed on the trackline could later be estimated. A fourth person recorded all sighting, effort and environmental data. Approximately every 30 minutes, the five scientists rotated between these four active positions and one resting position. All observers had previous experience in identifying cetacean species from aerial and/or shipboard surveys.

### Data recording

A laptop computer connected to a *LORAN* navigational receiver was used to record survey data. During the survey, a continuous record of position (updated every few seconds), altitude, airspeed and survey conditions was maintained. Conversation in the aircraft was recorded on a central cassette recorder to provide a complete record of activities. In addition, observers recorded individual sighting information into personal notebooks.

### Environmental conditions

Environmental conditions were recorded throughout the survey whenever changes occurred. Sea state was recorded using the Beaufort scale; surveys were conducted only in sea states 0–4. Sky condition was recorded as a percentage of cloud cover between the viewing area and the sun. Glare (due to sun or cloud reflections) was recorded separately by each observer as a percentage of the viewing area obscured. Water colour was categorised as dark blue, light blue, or green, based on comparison with colour plates of known hue and intensity. Presence/absence data was recorded for haze below the aircraft and for kelp on the water surface.

### Sighting procedures

When sightings were made, the aircraft's position was recorded along with information on species identification, the observer who made the sighting and the declination angle to the center of the school (measured with a clinometer). All observers then concentrated on identifying the sighted species and estimating school size while the aircraft circled over the animals. School size was defined to include the animal(s) initially sighted as well as any additional subgroups judged to belong to the same school (i.e. travelling in the same direction or belonging to the same feeding aggregation). Fluorescein dye markers were dropped as necessary to aid in the relocation of animals. Navigation and position features in the data entry program were also used to relocate animals, and to return to the same location on the trackline after all sighting information had been collected. Any additional schools sighted while diverted from the transect were recorded as 'off effort' sightings and were not used for abundance estimation.

Species identification was discussed and agreed upon by all observers. When it was not possible to identify animals with certainty, a code or combination of codes reflecting the possible identification of the animals was entered. A flowchart of the species codes used is shown in Fig. 2. High, low and best estimates of school size were recorded separately by all observers who were able to obtain an estimate. To avoid influencing each other, the observers wrote their estimates into personal notebooks without discussing them. At the end of the day, the survey leader entered all estimates into the data files.

Sighting procedures were essentially the same for the primary and secondary observers, except that the secondary observer waited approximately 10 seconds after sighting animals before announcing them, in order to ensure that they had passed the field of view and were missed by the primary team. Additionally, due to space

limitations in the belly viewing port, the secondary observer estimated sighting angles from marks previously applied to the window, rather than using a clinometer.

## ANALYTICAL METHODS

### Data stratification

The study area was divided into four *a posteriori* geographic areas based on survey coverage and species distributions. This was necessary because we were not able to complete both grids in all areas and the resulting coverage was not uniform throughout the study area. As species distributions were also not uniform, it was inappropriate to estimate abundances over the entire region.

Although environmental conditions such as sea state and percentage of cloud cover were recorded throughout the survey and have been shown to influence cetacean sighting rates (Holt and Cologne, 1987; Forney *et al.*, 1991), it was not possible to stratify the data by these criteria due to insufficient sample sizes. It is expected that addition of data from the second survey year will provide sufficient information to evaluate the effects of environmental conditions.

Sightings of unidentified species have either been excluded from abundance calculations (Wade and Gerrodette, 1992), or they have been assigned to individual species based on the proportion of sightings of each species (Holt and Sexton, 1989; Wade and Gerrodette, 1993). Neither approach is satisfactory for this analysis due to the small number of sightings made during the survey and the non-uniform distribution of some species throughout the study area. To maximise sample sizes without relying on imprecise estimates of species proportions, sightings of unidentified species were assigned a species code based on the geographically closest identified sighting of a candidate species (see Fig. 2). For example, a school of dolphins identified as 'whitebellies' (indicating they were either Pacific white-sided (*Lagenorhynchus obliquidens*), striped (*Stenella coeruleoalba*) or common dolphins), was assigned to one of these three based on the identity of the species which had the closest identified sighting. Due to the rarity of beaked whale sightings, and the general difficulty in resighting and identifying them to the species level during surveys, only a combined abundance estimate was obtained for this group.

The small number of sightings also made it necessary to pool distributions of perpendicular sighting distances to estimate the detection probability density function for line transect calculations. Other researchers have pooled across species or species stocks with similar sighting characteristics (Holt and Sexton, 1989; Wade and Gerrodette, 1992). Sighting characteristics are generally evaluated based on body size, group size, behaviour, associated animals and other sighting cues. In particular, group size is known to influence detectability of groups (Drummer, 1985; Holt and Sexton, 1989), so only species with similar group sizes should be pooled.

Preliminary groups were created based on considerations of school size, body size and behaviour. These groups were then evaluated using a Kolmogorov-Smirnov test, and only if distributions of perpendicular distance were not significantly different from one another were the groups pooled. This resulted in the following three species/group size categories for abundance estimation: (1) small cetacean groups with 1–10 animals; (2) small cetacean groups with more than 10 animals; and (3) medium and large cetaceans. The species in these groups are given in Table 1.

Table 1

Assignment of species to three species/group size categories for estimation of f(0) and g(0). N = number of sightings in each category.

| Species | Group size | N | f(0) | g(0) |
|---|---|---|---|---|

In summary, the data for each species were divided into either four or eight strata, defined by four areas and one or two group size categories. Species-specific abundances were calculated separately for each stratum and then combined to obtain overall population estimates.

**Abundance estimation**

Line transect methods (Burnham *et al.*, 1980) were applied to estimate abundances separately for each stratum. A modification of the standard formula used to estimate the density of animals, corrected for the probability of missing animals on the trackline (Buckland *et al.*, 1993), was used here to estimate the abundance of each species:

$$N = \sum_{j=1}^{3} \sum_{i=1}^{4} \frac{n_{i,j} s_{i,j} f_j(0)}{2 L_i g_j(0)} A_i, \qquad (1)$$

where

$N$ = estimate of the total number of animals of the species in the study area;

$n_{i,j}$ = number of sightings of the species in Area $i$ and species/group size category $j$;

$s_{i,j}$ = average group size of the species in Area $i$ and species/group size category $j$, calculated as the total number of animals in all groups divided by the number of groups sighted;

$f_j(0)$ = the probability density function evaluated at zero perpendicular distance for species/group size category $j$;

$g_j(0)$ = the probability of detecting a group of animals on the trackline for species/group size category $j$;

$L_i$ = the length of transect surveyed in Area $i$ (in km);

$A_i$ = the size of Area $i$ (in km$^2$).

Values for $f(0)$ were obtained for each species/group size category by fitting the distribution of all perpendicular sighting distances (primary and secondary) to the Hazard rate model with the program *HAZARD* (Buckland, 1985).

**Correction for missed animals,** $g(0)$

Standard line transect theory generally sets $g(0) = 1$, assuming that all animals on the trackline are seen. However, in aerial surveys for cetaceans, animals on the trackline are likely to be missed due to two factors: (1) animals at the surface may not be seen by the observers; and (2) animals which are submerged when the aircraft passes cannot be seen by observers. These two types of visibility bias have been called perception bias and availability bias, respectively (Marsh and Sinclair, 1989).

Availability bias has been corrected in the analysis of harbor porpoise line transect data, based on studies of dive patterns of individual animals (Barlow *et al.*, 1988; Calambokidis *et al.*, 1992). However, the proportion of time a school is visible will depend not only on dive patterns of individuals, but also on the size of the group (Holt and Cologne, 1987). Separate correction factors for different species and/or school sizes are difficult and expensive to obtain, and are not currently available. In this analysis, no correction for availability bias could be made.

Perception bias in line transect surveys has been addressed through independent observer experiments, which use additional observers on secondary platforms, such as additional aircraft, vessels or land-based observation points (Hiby and Hammond, 1989; Calambokidis, 1990), or add a second observer team on a single survey platform (Butterworth and Borchers, 1988; Hiby and Hammond, 1989; Øien, 1990).

In this study, the first approach was not feasible due to the high cost and logistic problems involved in having a second aircraft or vessel nearby to identify missed animals. Furthermore, the need to circle over each group of animals sighted for identification and enumeration made it impossible to have two fully independent observer teams within the aircraft. For these reasons, we opted for a partially independent observer design, wherein the secondary observer called out sightings only after they had been missed by the primary team. This enables estimation of a maximum correction factor for the fraction of animals missed by both teams.

The fraction of animals seen on the trackline by both teams combined, $g_{Tot}(0)$, can be expressed as:

$$g_{Tot}(0) = g_P(0) + g_S(0)\,(1\text{-}g_P(0)) \qquad (2)$$

where the subscripts $P$ and $S$ represent the primary and secondary teams, respectively. Although both $g_{Tot}(0)$ and $g_S(0)$ are unknown, the ratio $g_{Tot}(0)/g_P(0)$ can be estimated as:

$$\frac{g_{Tot}(0)}{g_P(0)} = \frac{n_{Tot}\, f_{Tot}(0)}{n_P f_P(0)} \qquad (3)$$

where

$n_{Tot}$ = number of sightings made by the primary and secondary teams combined;

$n_P$ = number of sightings made by the primary team;

$f_{Tot}(0)$ = probability density function evaluated at zero perpendicular distance for primary and secondary sightings combined;

$f_P(0)$ = probability density function evaluated at zero perpendicular distance for primary sightings.

We assume that the secondary observer misses no more than the primary observers on the trackline ($g_S(0) \geq g_P(0)$). Therefore, the following inequality, in terms of the known ratio $g_{Tot}(0)/g_P(0)$, can be derived from Equation (2) for the expected fraction of animals on the trackline seen by at least one observer team:

$$g_{Tot}(0) \geq \left(2 - \frac{g_{Tot}(0)}{g_P(0)}\right) \frac{g_{Tot}(0)}{g_P(0)} \qquad (4)$$

The two sides are equal when $g_S(0) = g_P(0)$. Using the above equations, the overall probability of detecting a group of animals on the trackline, $g_{Tot}(0)$, was estimated for each of the three species/group size categories. Because the view of the trackline from the belly (secondary) observer position is better than from the side (primary) positions, $g_{Tot}(0)$ is expected to represent the minimum proportion seen.

**Variance estimation**

Variance in the abundance estimates was calculated using bootstrap techniques applied to the complete data set. The data were subdivided by area into segments of effort of equal length. To investigate possible effects of the choice of segment length on estimates of variance, values of 5km, 10km, 15km and 20km were tested. The segments were drawn randomly with replacement until the total number of kilometers actually surveyed in each area was reached. This process was repeated 1,000 times for each segment length.

Each replicate was treated and analysed as a separate survey. Sightings were first stratified into the three above species/group size categories. Individual values for $n$ and $s$ were calculated, and $f(0)$ was estimated with the program *HAZARD*. The correction factor $g(0)$ estimated for the actual survey data was used for all bootstrap calculations, and was assumed to be known without error. Uncorrected (assuming $g(0)$=1) and corrected (using the estimated correction factor $g(0)$) abundance estimates for each species were then calculated for each replicate. The variance, coefficient of variation and percentile confidence limits (Buckland, 1984) were obtained from the distribution of the 1,000 bootstrap abundance estimates using standard formulae.

## RESULTS

A summary of all completed survey effort, stratified by Beaufort sea state and percentage cloud cover, is shown in Table 2. Due to unusually stormy weather during the survey period, only approximately 85% (5,309km) of transect Grid 1 and 27% (1,724km) of Grid 2 were completed, for a total of 7,033km. Fig. 3 shows the completed transects and the four *a posteriori* areas used for stratification. Approximately uniform effort was achieved within each area stratum. A total of 126 cetacean sightings were made while on effort (actively searching), and an additional 29 sightings were made while off effort (in transit or circling). The locations of all 155 cetacean sightings made during the survey are plotted in Fig. 4. Sighting information stratified by area and species is summarised in Table 3.

Positive species identification was not possible for 21 of the 126 'on effort' sightings. Four of these sightings were identified as ziphiid whales, for which a combined abundance estimate will be obtained, and no individual species assignment is required. For the remaining 17 sightings, assignments to individual species are shown in Table 4. In one case, the animals were identified as belonging to the genus *Balaenoptera* and could be narrowed down to one of three species: fin whale (*B. physalus*), sei whale (*B. edeni*) or Bryde's whale (*B. borealis*). However, none of these three species were otherwise sighted during the survey, and no individual species could be assigned.

Table 2

Survey effort (in kilometers) stratified by sea state and % cloud cover.

| | Beaufort sea state | | | | |
|---|---|---|---|---|---|
| % Cloud cover | 0&1 | 2 | 3 | 4 | Total |
| 0-24 | 211 | 911 | 1,917 | 1,339 | 4,378 |
| 25-49 | 26 | 66 | 96 | 85 | 273 |
| 50-74 | 45 | 58 | 326 | 241 | 670 |
| 75-100 | 76 | 129 | 978 | 529 | 1,712 |
| Total | 358 | 1,164 | 3,317 | 2,194 | 7,033 |

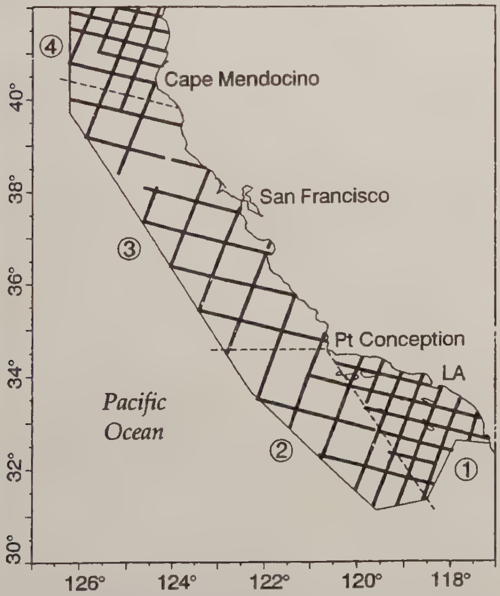

Fig. 3. Completed transects (solid lines) and *a posteriori* geographic strata (separated by dashed lines) used in the analysis. Area numbers are shown in circles.

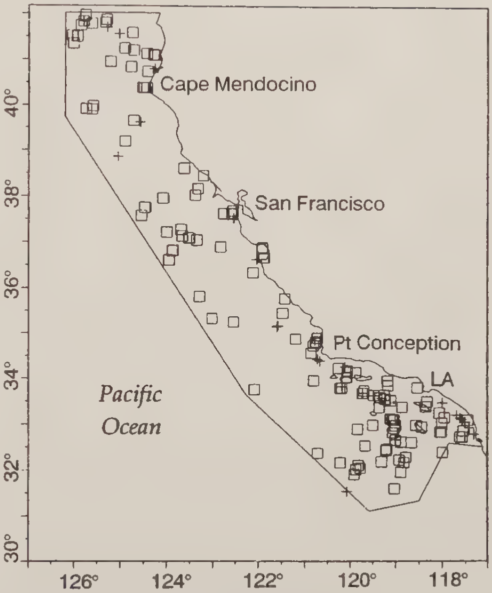

Fig. 4. Locations of all 155 cetacean sightings made during the survey. The 126 'on effort' sightings (used in the abundance estimation) are shown by squares, and the 29 'off effort' sightings (made while circling or in transit) are shown with plus signs.

Distributions of perpendicular distance from the trackline for individual species (based on both primary and secondary sightings) were combined into the three species/group size categories defined above (Analytical Methods section), based on similarities in the distributions. The Hazard model fit to the perpendicular distance distributions for each of the three categories is shown in Fig. 5. The probability of detecting a group of animals on the trackline, $g(0)$, was estimated separately for the three species/group size categories. Table 1 shows the assignment of individual species to the three groups, along with the estimates of $f(0)$ and $g(0)$.

Corrected and uncorrected abundance estimates along with estimates of precision are shown in Table 5. The chosen length of the sampling unit (5, 10, 15 or 20km) for the bootstrap simulation did not appear to influence the estimates of precision (Fig. 6), although for two species, the smallest segment length produced slightly different values than the other three. The percentile confidence limits and the CVs shown in Table 5 are taken from the bootstrap with a segment length of 20km.

## DISCUSSION

The estimates of abundance obtained from this survey are preliminary. They represent data from the first of two surveys which were designed to yield a combined level of

Table 3

Summary of on effort sighting information for all species seen by area. Survey effort is 1,862km for Area 1, 1,362km for Area 2, 2,552km for Area 3 and 1,290km for Area 4. Multi-species sightings are listed once for each species, so the totals are higher than the actual number of sightings.

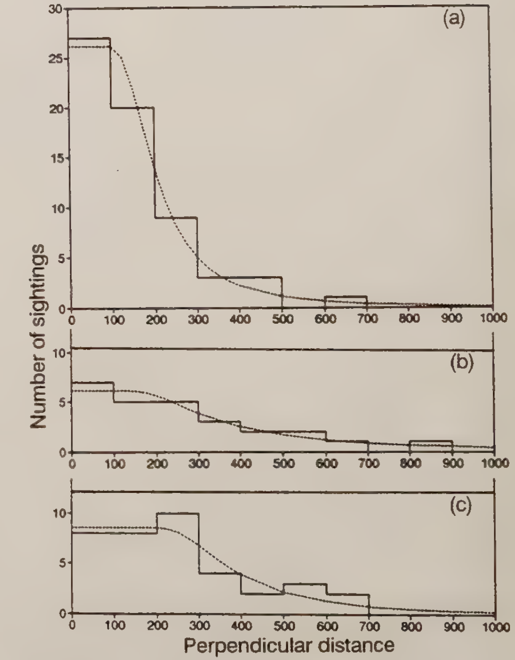

Fig. 5. Distribution of perpendicular sighting distances (100m intervals; solid line) and Hazard model fit (dotted line) for (A) small cetaceans in groups ≤10, (B) small cetaceans in groups >10, and (C) medium and large cetaceans.

precision in the abundance estimate corresponding roughly to a coefficient of variation of 0.36 for the common species. As expected, precision is lower than this after just one survey. However, these new abundance estimates are believed to be superior to other currently available estimates (Dohl *et al.*, 1978; 1983) for two reasons: (1) previous estimates do not include levels of precision; and (2) previous estimates are based on data which were collected over 10 years ago, and species distributions and abundances may have changed. For example, short-finned pilot whales, *Globicephala macrorhynchus*, which formerly were seen regularly along the California coast, were not sighted at all during this survey. Both of these factors introduce uncertainty which makes these previous estimates less useful for management purposes.

Although the variability in the presented estimates is quite large (CVs ranging from 0.28 to 1.07), it is likely to decrease considerably with data from the second survey,

Table 5

Uncorrected (U) and corrected (C) abundance estimates (N) for all cetacean species sighted during the 1991 aerial survey in California. Bootstrap estimates of precision are presented in terms of the 95% confidence limits and the coefficients of variation (CV) for the bootstrap simulations with segments of 20km length. The correction factor is assumed to be known without error.

particularly for the small cetaceans. The precision of estimates for some of the larger whales is expected to remain low due to the small numbers of sightings. However, abundance estimates for several species of the larger whales have been obtained with other, more efficient methods, such as photo-identification studies (blue and humpback whales: Calambokidis *et al.*, 1991) or land-based census techniques (gray whales: Reilly, 1984; Buckland, 1993).

Several sources of potential bias must be addressed. In this analysis, we have attempted to assess the magnitude of perception bias and correct for it in the abundance estimates. The estimated maximum proportion of animals missed ranges from 0.024 to 0.218 of all sightings, depending on group size and body size of the animals. If no other biases were occurring, the best point estimate would lie between the uncorrected and corrected values in Table 5. However, availability bias could not be corrected for in this analysis. This should produce a downward bias in the abundance estimate, whose magnitude will vary between species. The bias is expected to be smallest for species which tend to occur in large groups, and largest for species which spend relatively less time at the surface.

Although line transect methods are robust to pooling different distributions (Burnham *et al.*, 1980), the pooling of all environmental conditions is likely to introduce a downward bias in the abundance estimation due to the lower probability of sighting animals on the trackline under poor conditions (Holt, 1987; Barlow *et al.*, 1988; Forney *et al.*, 1991). The magnitude of this bias is unknown, and is likely to vary between species. Our method of correcting for missed groups may account for some of this bias, but may not be robust to heterogeneity in the fraction missed due to environmental conditions.

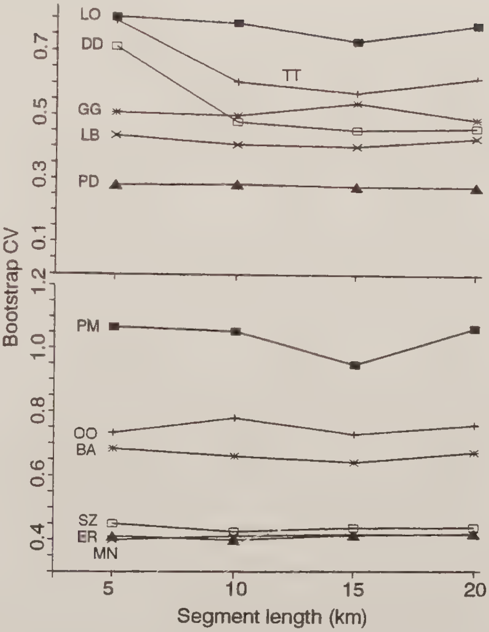

Fig. 6. Coefficients of variation (based on 1,000 replicates) for simulations using bootstrap segment lengths of 5km, 10km, 15km and 20km. See Fig. 2 for key to species codes.

Potential upward bias in line transect analysis can result if factors other than distance to the trackline affect the probability of seeing a school. School size has been shown to affect the probability of detection (Drummer, 1985; Holt and Sexton, 1989), and this can lead to an upward bias in the abundance estimate (Quinn, 1985; Drummer and McDonald, 1987). To counteract this effect, we have stratified small cetacean sightings by group size and estimated abundances separately for small and large groups of the same species. This is an artificial separation, but it reduces potential biases due to large variation in group size within a single species.

In summary, three sources of downward bias and one source of upward bias in the abundance estimates have been identified. We have corrected for one of the sources of downward bias (perception bias), and attempted to minimise the upward bias by a post-stratification by school size range. Overall, our estimates may still be biased downward.

When comparing the current abundance estimates with those made previously by other researchers, the differences vary between species. Estimates for Pacific white-sided dolphins and Dall's porpoise, for example, are similar to previous values of approximately 26,000–86,000 and 3,000–9,000, respectively (Dohl *et al.*, 1978; 1983). The corrected estimate of 405 humpback whales is also similar to recent estimates based on photo-identification work (Calambokidis *et al.*, 1991), despite differences in seasonal timing of these studies. Other species previously recorded were not seen at all during this aerial survey (e.g. short-finned pilot whales) and some were seen in greater numbers than before. The most notable disagreement is for common dolphins, with the current corrected winter estimate (277,783) being more than an order of magnitude larger than the previous value of 15,488 (CV=0.36; Dohl *et al.*, 1986). The validity of the new estimate is supported by the 1991 summer/fall estimate from a ship survey, which is also in the hundreds of thousands of animals (Barlow, 1993).

Two of the species for which abundance estimates were made occur in two distinct forms in California waters. The two forms of common dolphins (offshore and neritic) are currently undergoing a taxonomic review and may be divided into two distinct species (Heyning and Perrin, 1991; Rosel, 1992; Dizon *et al.*, In press). Although clear differences in color pattern, size and beak length exist between these two forms, it is not always possible to differentiate them from the air, and the abundance estimate here is a combined estimate. If future assessments require separate estimates for the two forms, aerial surveys may not be adequate.

The second species which occurs in two forms is the bottlenose dolphin, which is divided into a coastal population found very close to shore along portions of the California mainland (Hansen, 1990; Maldini, 1991), and an offshore population, which is distributed more widely in offshore waters (Hansen, 1990). All of the animals seen during this survey were at least several miles from the mainland, so the estimate presented here is assumed to represent the population of offshore animals. Separate aerial surveys are currently being conducted by NMFS to assess year-round abundance of the coastal bottlenose dolphin.

Estimates for harbor porpoise and gray whales are substantially lower than previous estimates (Reilly, 1984; Barlow, 1988; Barlow *et al.*, 1988; Buckland, 1993). This is likely to be due to the fact that the defined study area is not appropriate for the range of these animals. Gray whales have a much larger range and migrate through California waters (southward and then northward) from roughly November to May. The current estimate can be thought of as that portion of the population which was migrating through California in March and early April. Harbor porpoise are limited to a narrow coastal band, and our tracklines only overlapped with this region at specific points. The overall sighting rates are therefore not representative of the total area in which harbor porpoise occur.

The estimates presented for the beaked whales as a group can be viewed as a combined estimate for whales of the genus *Mesoplodon* and *Ziphius cavirostris*. All unidentified beaked whale sightings could be narrowed down to these two genera. The only other beaked whale species known to occur in this region, *Berardius bairdii*, can be readily distinguished based on its size and was not sighted during this survey.

In summary, although we were not able to complete the two full survey grids as planned, sightings were sufficient for most of the small cetacean species and for the beaked whales as a group to obtain reasonable estimates with confidence limits. The analysis indicates that precision is likely to reach acceptable levels when data from the 1992 aerial survey are included. Coupled with the summer/fall ship survey estimates, these studies will provide valuable insights into seasonal changes in distribution of cetaceans along the California coast, as well as potential historical changes. Given the uncertainty in abundance estimates, we stress the importance of presenting confidence limits. Bootstrap percentile confidence limits may be improved upon in the future with more advanced bootstrap procedures (Efron, 1987). Sensitivity of the estimates to our method of assigning 'unknown' sightings to species also requires examination. Furthermore, surveys must be designed with a target level of precision in mind to ensure that an appropriate level of survey effort is completed.

## ACKNOWLEDGEMENTS

Funding for this project was provided by the Office of Protected Species, US Department of Commerce. The aircraft was provided by the NOAA Office of Aircraft Operations Center. We express special thanks to the project pilots, T. O'Mara, J. Vance, P. Wehling and M. White. We are grateful to the meteorological staff of the National Weather Service for their valuable assistance in planning flights. Observers were J. Carretta, S. Kruse, C. LeDuc and R. LeDuc (also K.A.F and J.B.). Survey design was improved by comments from D. Ainley, H. Braham, S. Buckland, K.P. Burnham, D. DeMaster, D. Goodman, T. Gerrodette, L. Hansen, W. Hoggard, D. Palka and T. Polacheck. Data recording software was developed by J. Cubbage (and J.B.). We thank D. DeMaster and T. Gerrodette (NMFS, Southwest Fisheries Science Center, P.O. Box 271, La Jolla, CA 92038), and L. Hiby for their critical reviews of an earlier version of this manuscript. Special thanks go to J. Cooke for his careful review and suggestions regarding the *g*(0) calculations.

# GLOBAL CLIMATE CHANGE AND HARMFUL ALGAL BLOOMS: THE EXAMPLE OF *Gymnodinium catenatum* ON THE GALICIAN COAST

**SANTIAGO FRAGA[1] and ANDREW BAKUN[2]**
[1]Instituto Español de Oceanografía, Apda 1552, 36280 Vigo, Spain; [2]Pacific Fisheries Environmental Group, P.O. Box 831, Monterey, CA 93942, U.S.A.

## ABSTRACT

A scenario is presented in which the incidence of blooms of the toxic dinoflagellate *Gymnodinium catenatum* on the coast of Galicia (NW Spain) could increase due to global climate change. Blooms of *G. catenatum* in the Galician rias appear to be related to the autumn relaxation of upwelling. This results in the incursion of warm, nutrient-depleted surface water into the rias, deepening the nutricline. Being a chain-former, *G. catenatum* is an effective swimmer and better adapted to vertical migration than other dinoflagellates. Thus, a deepening of the nutricline may favor this species which is capable of migrating to the deep layers to take up nutrients. It is expected that atmospheric "greenhouse" effects will intensify equatorward wind stress along the west coast of the Iberian Peninsula during spring and summer, thereby amplifying coastal upwelling. This would increase the temperature difference between recently upwelled waters and surface waters of oceanic origin, and enhance primary production and mussel growth within the rias during summer. The estuarine circulation of the rias would then export increased particulate organic matter (phytoplankton and mussel feces) from the rias. This organic matter would tend to settle and remineralize on the continental shelf near the mouth of the rias, increasing the nutrient concentration of the waters entering the rias below the nutricline. The combination, during fall, of increased nutrient concentrations below a deepened nutricline and a more strongly stratified water column would seem to be particularly favorable to *G. catenatum*. The first recorded observation of this species was in 1976 when the first PSP outbreak associated with Galician bivalves was also reported. Conversely, *Gonyaulax polyedra*, a common bloom species in the past, is now rare in the rias.

## INTRODUCTION

Recent decades have seen a continuing build-up of $CO_2$, methane, chlorofluorocarbons, and other greenhouse gases in the earth's atmosphere. The scientific consensus is that substantial global warming and other important climatic effects are likely [1]. There is growing concern that associated changes in the coupled atmosphere-ocean system, brought about by this accumulation, may have major effects on marine ecosystems, their living resources and associated human cultural and economic values. One "greenhouse effect" which seems certain is an increase in temperature contrast between the heated continental land masses and the oceans during the warmer seasons of the year. This would lead to amplified sea breeze circulations and alongshore coastal winds, correspondingly enhanced offshore Ekman transport in the ocean surface layer, and intensified coastal upwelling [2].

Another important global trend related to human activities is the increased economic and public health problems related to harmful algal bloom phenomena [3]. Although these trends have not been linked mechanistically, the potential for linkage of global climate change to the harmful bloom problem is certainly of great interest.

The ocean adjacent to the west coast of the Iberian Peninsula is a "classic" eastern ocean coastal upwelling system. The upwelling process is highly seasonal, being most intense in spring and summer, but relaxing during fall and winter [4]. Nutrient-rich, upwelled waters provide a basis for high rates of organic production, a rich trophic pyramid and important local fisheries. Major mariculture operations occur in the Rias Bajas, a series of oceanic bays on the coast of Galicia (Fig. 1), where intermittent enrichment during upwelling events supports intensive raft culture of mussels [5]. The toxic dinoflagellate *Gymnodinium catenatum* Graham was first observed in October, 1976, coinciding with the first recorded outbreak of paralytic shellfish poisoning (PSP) in Spain [6]. Over the past decade, PSP outbreaks have become a serious threat to the local mariculture industry.

This paper utilizes recent advances in understanding the ecology of chain-forming dinoflagellates, such as *G. catenatum*, and the likely effects of global climate change on coastal upwelling ecosystems, such as the Galician Coast, to provide an example of a credible scenario for linkage of global climate change and harmful algal bloom phenomena. The goal is to stimulate discussion and motivate interdisciplinary research activity on a topic of potentially serious socio-economic and public health concern.

## CLIMATE CHANGE AND UPWELLING ECOSYSTEMS

Eastern ocean upwelling ecosystems are the most productive, extensive ocean areas of the world. In such regions, equatorward alongshore winds cause offshore transport in the surface Ekman layer. This loss of surface water near the coast is balanced by upwelling of cool, nutrient-rich waters from depth. During active upwelling, the offshore surface Ekman flux maintains a slight sea surface slope implied by the density difference between the upwelled water near the coast and the lighter surface waters a short distance offshore. However, during relaxations or reversals in upwelling-producing wind stress, the lighter oceanic surface water tends to collapse coastward [7], overrides the newly upwelled water, and downwells at the coast. Downwelling has been observed to extend to within the Rias Bajas, following the initial seasonal relaxation of upwelling along the Galician coast [8].

The vigorous alongshore wind that drives the upwelling is supported in part by a strong atmospheric pressure gradient between a thermal low pressure cell that develops over the heated land mass and the higher barometric pressure offshore over the cooler ocean. This is one reason why upwelling seasons tend to encompass nearly the entire year in tropical eastern ocean boundary systems but, with increasing latitude are more restricted to a late spring to summer period [4]. Greenhouse-related amplification of heating during spring and summer would intensify the thermal low pressure cell, enhancing the onshore-offshore pressure gradient. The stronger pressure gradient would strengthen the alongshore geostrophic wind, causing enhanced offshore Ekman transport and amplified coastal upwelling. The increased upwelling and mixing implied by such a wind increase, by cooling the coastal ocean surface layers and further accentuating the ocean-continent temperature contrast, might constitute a positive feedback loop [2] further amplifying the effect.

Eastern sides of oceans have a much drier atmosphere than western sides. Since the most important greenhouse gas in the atmosphere is water vapor, the global accumulation of $CO_2$, methane, chlorofluorocarbons, etc., will have a larger relative greenhouse effect along eastern ocean boundaries than in other ocean regions. Thus, one would expect the effect to emerge from the "noise level" of natural, short term climatic variability earlier in these regions than elsewhere. However, since the effect on the wind system is to increase upwelling and mixing (both of which cool the sea surface), it is not surprising that general increases in average sea surface temperature have not been an evident consequence in these systems. On the other hand, the intensity of upwelling-producing wind stress (Fig. 2) off the Iberian Peninsula has appeared to increase dramatically during spring and summer over the past four decades [2, 9, 10]. During this period, a sustained increase in spring-summer alongshore sea level slope (relative to fall-winter) (Fig. 2d) tends to corroborate this trend. These and various other aspects of the seasonality and geography of wind stress trends throughout the North Atlantic conform well to a greenhouse effects scenario [10].

d. Sea Level Slope

FIG. 2: Long term (1946-1990), increasing trends in upwelling-producing wind stress and alongshore sea level slope (after [10]). Panels a, b, c: spring-summer (April to September) average monthly wind stress (dyne $cm^{-2}$) for three locations (a, b, c) off the Iberian coast (see FIG. 1). Long-term mean for each series indicated by horizontal, dashed line. Linear trend lines fitted by least squares. Panel d: seasonal (spring-summer minus fall-winter) difference in sea level slope (in mm) between Cascais and (minus) Vigo (see FIG. 1).

## ECOLOGY OF *Gymnodinium catenatum* IN THE RIAS BAJAS

In a study of nutrient dynamics within the rias, Fraga [11] provided the scenario diagrammed in Figure 3: "In spring the upper levels of the NACW (North Atlantic Central Water) rise above the level of the bottom of the Rias, and nutrient-rich water reaches the photosynthetic layer inside the rias leading to high primary production. Part of the biomass produced is transported in the surface layer towards the mouth of the rias, sinks to the bottom, and decomposes. This enriches the deep water, which flows back into the rias." A relationship exists between mussel production within the rias and intensity of coastal upwelling outside the rias [12], based on a comparison of a mussel-condition index (% solids) and an upwelling index [13] computed from the atmospheric pressure gradient at a point 150 km off Cape Finisterre. Thus, the amount of particulate solids involved in the transport, sinking, decomposition, and remineralization loop (Fig. 3) would tend to increase with upwelling intensity.

*G. catenatum* blooms in the Galician Rias have been associated with the autumn relaxation of the summer upwelling [14, 15]. In late summer, sea surface temperatures in the rias are relatively cool due to the influence of coastal upwelling. Offshore, warm and salty water related to a coastal current [16] occurs at the surface. When the prevailing southward winds, which drive summer upwelling, relax or turn northward in the fall, the surface waters held offshore by the wind-induced offshore Ekman flux collapse toward the coast causing downwelling in the rias. Phytoplankton dominance then changes from diatoms to dinoflagellates. *G. catenatum* is one of the dinoflagellate species that may bloom at this time (see Fig. 2 in [17] ). When this occurs, mussels may become toxic to humans [14].

Vertical migration is an important factor in dinoflagellate blooms. *G. catenatum*, as observed during a bloom in the Ria de Vigo in 1986 [8], is able to undertake daily vertical migrations to transport nutrients from the deep nutricline to the illuminated surface layers for use in photosynthesis. In Galicia, *G. catenatum* commonly blooms together with *Alexandrium affine* in areas of downwelling, inside or near the mouths of the rias. These two species and other "red tide" dinoflagellate species can form long chains. Fraga *et al.* [18] reported that the swimming speed increases with chain length. This apparent hydrodynamical advantage results in the chain-forming dinoflagellates being better adapted for vertical migration than single-celled forms. (We diagram this "fall" scenario in Fig. 4). The advantage may be substantial when significant downwelling is occurring and/or the nutricline is deep. Thus, the depth of the nutricline appears to be a selection factor for chain-forming species over single-celled dinoflagellates or non-motile phytoplankters such as diatoms.

## A SCENARIO LINKING CLIMATE CHANGE TO TOXIC BLOOMS

The following "linkage scenario" is accordingly proposed. If climate change leads to increased upwelling intensity, the input of nutrients and primary production in the rias will increase during the upwelling season (April - September). The production of particulate organic matter, notably increased fecal matter from increasingly well-nourished mussel culture, will also increase and enter the transport, sinking, decomposition, and remineralization "loop" (Fig. 3). This would result in a greater accumulation of decaying organic matter on the bottom. Subsequent remineralization would increase nutrient concentrations in the layer beneath the deep nutricline following the upwelling season (Fig. 4). Vertically-migrating, chain-forming phytoplankters, such as *G. catenatum*, would have the best access to this increased deep nutrient pool.

FIG. 4: Diagram of nutrient dynamics after fall relaxation of upwelling. Lighter oceanic surface waters collapse toward the coast producing a downwelling zone in the rias which cuts off upwelled enrichment of the photic zone and depresses the nutricline. Vertically-migrating dinoflagellates may access the nutrient pool beneath the nutricline and transport assimilated nutrients to the photic zone for use in photosynthesis.

In addition, an increased upwelling intensity would be expected to increase the equatorward sea surface slope along the Iberian Peninsula. Thus, the initial collapse of the offshore surface water towards the coast upon cessation of the upwelling wind would tend to be intensified. (An increased southward, alongshore sea surface slope would increase the tendency for coastward geostrophic flow and tend to break down (by opposing southward momentum) maintenance of the offshore sea surface slope by Coriolis force, which holds the lighter oceanic surface waters offshore). This would enhance the episodic, fall downwelling within the rias and deepen the nutricline, favoring forms such as *G. catenatum* which are adapted for vertical migration.

As noted above, there is evidence that both upwelling intensity and seasonal (upwelling vs. non-upwelling) differences in sea level slope are indeed increasing along the Iberian coast and in other eastern ocean boundary regions. An apparent change in bloom species has also been observed [19] in the Rias Bajas. The first known reports of "red tides" in Galicia are from 1916 and 1917 [20], with the next report from 1955 [21]. In these three earlier blooms, *Gonyaulax polyedra* was the main species, but is now rare in these waters. In fact, several species which now form "red tides" in the rias (*G. catenatum*, *A. affine*, *Prorocentrum triestinum*, *Heterosigma akashiwo*) were not reported before the last decade. The hypothesis that these species represent recent introductions has been popular, given the introduction of viable dinoflagellate resting cysts into Tasmanian waters from the ballast waters of large cargo ships [22]. Admittedly, climate change is not the only potential explanation. The environment within the rias has been subjected to substantial alterations within this century. The human population inhabiting the shores of the rias has increased dramatically and mussel culture, initiated in the 1950s, has substantially altered nutrient dynamics in the rias.

Although aspects of this proposed scenario linking toxic bloom phenomena to global climate change are speculative, it represents a logical sequence of reasonably likely circumstances. The possibility emerges that an affect on harmful algal bloom phenomena may be one of the most direct consequences of climate change with regard to impacts on marine ecosystems and associated human values. There presently seems to be a nearly total absence of focus on this problem area within the various national or international global climate change research programs. It would, therefore, seem prudent to seek ways to encourage the design and implementation of expanded research activities in this area.

# WILDLIFE SOFTWARE

## TRENDS: SOFTWARE FOR A POWER ANALYSIS OF LINEAR REGRESSION

**TIM GERRODETTE,** *Southwest Fisheries Science Center, National Oceanic and Atmospheric Administration, P.O. Box 271, La Jolla, CA 92038*

Linear regression often is used in wildlife studies to assess trends. A typical use would be to assess growth or decline in population size over time. However, before commencing a program to monitor populations, several questions should be considered: (1) how many years should monitoring continue to detect a change; (2) how precise must an index be; (3) how large a change can be detected; and (4) what is the probability of detecting a change (obtaining a significant slope to the regression line), given that a change really is occurring?

Posing such questions is fundamental to a well-designed monitoring program. Obtaining answers through a statistical power analysis is important during both the design and analysis stages of a study. Tables (Cohen 1988) and microcomputer software (Goldstein 1989) are available to perform power analyses for many common statistical tests. We developed power analysis software for linear regression (program TRENDS) while designing surveys for dolphins (*Stenella* spp.) in the eastern tropical Pacific Ocean (Gerrodette 1987, 1991; Holt et al. 1987). TRENDS will be useful to biologists designing field studies, but it also could be used by teachers and students in courses on experimental design and statistics.

TRENDS is simple to use and parametrizes the problem in easily understood terms. It can be applied in any situation where linear regression analysis is appropriate, and where estimates of the dependent variable are made at equal (or nearly equal) intervals. Thus, the program is not limited to detecting trends in a time series of population size, but could be applied generally to any variable of interest measured at equal intervals. The program is a single file (TRENDS.EXE) executable on any IBM-compatible microcomputer. Input and output are via ASCII files created by the program; no graphics are produced. Source code is Microsoft FORTRAN 77.

TRENDS summarizes the power analysis in 5 parameters: (1) $n$, the number of sampling occasions (points in the regression); (2) $r$, the rate of change between each sampling occasion (slope of the regression line); (3) $CV1$, the coefficient of variation (ratio of standard deviation to mean, a measure of precision of estimation on each sampling occasion); (4) $\alpha$, the significance level (probability of a Type 1 error); and (5) power ($1 - \beta$, where $\beta$ is the probability of a Type 2 error). The value of any parameter can be estimated if the other 4 are specified. The parameter of interest depends on the particular application.

The relationships among these parameters are affected by several other factors: (1) whether change is linear or exponential, (2) whether change is positive or negative, (3) whether the statistical test is 1- or 2-sided, (4) how the precision of the estimates depends on abundance, and (5) which statistical distribution is used. The latter 2 factors depend on the method used to estimate abundance (line-transect surveys, mark–recapture methods, etc.) and the error structure of the estimates. TRENDS allows the user to choose among several possibilities.

The following example of the use of TRENDS is based on data presented in Storm et al. (1992). They found a mark–resight method superior to an area-conversion method for estimating white-tailed deer (*Odocoileus virginianus*) density, and stated that "we expect to continue monitoring the herd size during the next 5 years" (Storm et al. 1992:201). Is the mark–resight method also superior to the area-conversion method for monitoring herd size? What trends in population size can we expect to detect in 5 years? Using data presented in Storm et al.'s (1992) Table 2, we can estimate that, with 90% power over a 5-year period at a significance level of $\alpha = 0.05$, the minimum detectable annual rate of growth is 25% with the mark–resight method and 27% with the area-conversion method (see the user's guide for details). Lower rates of growth have a <90% chance of being detected in 5 years. Reformulating the problem to estimate the probability of detecting a 10%/year rate of herd size growth over a 5-year period yields detection probabilities (power) of 0.41 for the mark–resight method and 0.29 for the area-conversion method. These answers are approximate, but they indicate that mark–resight provides a slightly more sensitive method of monitoring deer herd size than area-conversion. Neither method, however, provides reasonable assurance of detecting a trend of 10%/year in 5 years. To detect such a trend with higher probability, we must expend more effort each year so that the herd size estimate has a smaller standard error, or we must continue monitoring for a longer period of time.

## Abstract

Endangered Hawaiian monk seal (*Monachus schauinslandi*) pups at all the major breeding islands in the Northwestern Hawaiian Islands have been tagged since the early 1980s. Pups were double flipper tagged as soon as possible postweaning. With few exceptions, an extensive tag resighting effort was conducted annually at the same islands. These resighting data were used to estimate seal survival rates from the time of tagging to age one at all locations using the ratio of seals alive in the second year to number of pups tagged. These survival rates among the islands, from weaning to age one, averaged over the years of the study, ranged from 0.80 to 0.90. For young seals over age one, capture-recapture methods were used to calculate survival pooled through several years, and these rates ranged from 0.85 to 0.98. At French Frigate Shoals and Laysan Island, the higher numbers of tagged pups allowed separate estimates of male and female survival to be calculated. These rates suggested that survival of immature females was better than males. Beginning in 1989, survival of immature seals at French Frigate Shoals declined sharply.

Key words: Hawaiian monk seal, *Monachus schauinslandi,* survival, tag resighting, Jolly-Seber.

The Hawaiian monk seal population has declined substantially in numbers since the first reliable range-wide counts were made in the late 1950s (Rice 1960; Johnson *et al.* 1982; NMFS, unpublished data). Concern over this decline led to the species being listed as endangered under the U.S. Endangered Species Act in 1976. In order to assess possible causes of the decrease, monitor the status of the population, and evaluate the efficacy of recovery actions, tagging of weaned pups was initiated on Kure Atoll in 1981 (Gilmartin *et al.* 1986), Lisianski Island in 1982 (Henderson and Johanos 1988), and then expanded to all other major breeding islands by 1984. efforts have involved long visits to most of the sites in subsequent years, resulting in resighting of a high fraction of the surviving tagged individuals. Assessment of survival from birth to weaning for the Hawaiian monk seal has been based on counts of dead pups of preweaning age recovered annually from the breeding islands. These data show preweaning survival among the breeding sites to be approximately 93% (NMFS, unpublished data).

The present paper reports survival rates among the five major monk seal breeding locations at Kure Atoll, Pearl and Hermes Reef, Lisianski and Laysan Islands, and French Frigate Shoals (Fig. 1) determined from the resighting data of pups tagged post-weaning.

## METHODS

*Pup tagging*—Beginning in 1981, weaned Hawaiian monk seal pups were tagged with colored and engraved plastic Temple Tags® between the fourth and fifth digit of each rear flipper as described by Gilmartin *et al.* (1986). A study to evaluate the effects of tagging weaned pups was conducted on Lisianski Island in 1982 utilizing a control group of weaned pups that were only marked with identifying numbers applied to the pelage with a commercial hair bleach when the seals were sleeping (Henderson and Johanos 1988). Results of this pilot study did not indicate significant differences between the tagged and control groups and enabled the pup tagging effort to be conducted at all breeding locations in subsequent years. Pups are double-tagged and lost tags are replaced soon after one tag is observed missing. Identities of seals based on photographs of scars and natural markings are also annually updated and cataloged. The latter effort provides a means of individual identification should both flipper tags be lost at the same time and assures that tag loss is of minor importance.

No tagging or resighting effort occurred at Lisianski Island in 1989, and abbreviated visits were necessary at Lisianski Island in 1988 and Pearl and Hermes Reef in 1990, reducing the number of pups tagged and the resighting effort for those years.

*Estimation of survival rates*—Although high annual resighting rates of tagged individuals were common, a few individuals were not seen in some intervening years, and others were identified at sites other than those at which they were tagged initially. Therefore, the most general capture-recapture model, the Jolly-Seber method (Seber 1982), was used for parts of the study. However, in most instances the very high resighting rates and fidelity to birth sites facilitated the use of much simpler estimation models, described by Haldane (1955) and Chapman and Robson (1960).

Even though nearly all of the weaned pups were tagged in most years, the low number of pups born annually at sites other than French Frigate Shoals resulted in small numbers being available for tagging, thus males and females were combined for many of the analyses. The small numbers also made it advantageous to use the simplest survival model available.

The simple model used here assumes a constant annual survival rate, and can be written as:

$$n_x = ps^x N \qquad (1)$$

where $N$ is the initial number tagged, $s$ is annual survival rate, $p$ is proportion of those present actually resighted in a given year, and $n_x$ is the number resighted in year $x$. Haldane (1955) used a similar geometric model but considered the numbers of tagged individuals dying in each year. Chapman and Robson (1960) gave an extensive analysis of the geometric distribution for use in estimating survival rates from a "catch curve"; *i.e.*, numbers of individuals of successive ages in a sample. Seber (1982: Sec. 5.4) gives a general model for tag recoveries from dead animals.

If one takes the natural logarithm of Equation 1, a linear equation results:

$$\log_e n_x = \log_e(pN) + x \log_e s, \qquad (2)$$

and this can be fitted by ordinary regression methods. This approach is not as satisfactory as methods based on Equation 1 because using Equation 2 on results of a tagging study is not likely to conform to the normal theory model for linear regression (Chapman and Robson 1960). However, some of the data of this study has missing years and years of low resighting rates, so the regression model is useful for provisional analyses of such data because these years can be excluded in the regression model.

Chapman and Robson (1960) gave an equation for the maximum likelihood estimator for a sequence of observations from a geometric distribution:

$$\frac{T}{n} = \frac{s}{1-s} - \frac{(k+1)s^{k+1}}{1-s^{k+1}}; \qquad (3)$$

where $k$ denotes the number of successive observations beyond the first used, $n = n_0 + n_1 + n_2 + \ldots + n_k$, where $n_i$ is the number of individuals observed on the $i$th occasion, and $T = n_1 + 2n_2 + \ldots + kn_k$. This equation must be solved by iteration.

Haldane (1955) considered the situation where several such sequences were combined. Using the notation above, his equation becomes:

$$\Sigma \left\{ \frac{T_j}{n_j} - \left[ \frac{s}{1-s} - \frac{(k_j+1)s^{k_j+1}}{1-s^{k_j+1}} \right] \right\} = 0; \tag{4}$$

with the variance estimate:

$$Var(s) = \left[ \Sigma \left\{ \frac{n_j}{s(1-s)^2} - \frac{(k_j+1)^2 s^{k_j-1} n}{(1-s^{k_j+1})^2} \right\} \right]^{-1}. \tag{5}$$

It should be noted that the above methods all assume that both $p$ and $s$ are constant throughout.

First-year survival rates were estimated differently. Long visits to each site and frequent observations resulted in very high resighting rates in most instances. Occasionally, an individual was not observed in a given year, but survivors were almost always seen in the second year. Consequently, "back-corrections" could be used after an interval of two or three years, and first-year survival calculated as the ratio of numbers alive in the second year over number of weaned pups tagged. For consistency, and to be virtually certain of the back-calculations, we based first-year survival estimates on data for cohorts tagged through 1987.

Pollock *et al.* (1990) note that estimates of the kind used here to calculate first-year survival may be subject to a negative bias. This possibility was evaluated by using equation 5.2 of Pollock *et al.* (1990) along with an equation for the probability that an individual will be sighted again given by Lebreton *et al.* (1992). Jolly-Seber calculations for sites other than Kure (where survival is very high and potential bias negligible) gave an average probability of sighting ($P$) of 0.98 at sites other than Pearl and Hermes Reef, where it averaged 0.95. Assuming a first-year survival rate of 0.8 and subsequent annual survival rates of 0.9, the bias was less than one percentage point of survival, and thus was neglected.

A Kure Atoll recovery project (Gerrodette and Gilmartin 1990) involved collection and rehabilitation of some emaciated female pups from French Frigate Shoals and release of them at Kure, so the first-year survival at French Frigate Shoals is based on the number of tagged pups less those removed for rehabilitation (listed separately in Table 1).

*The Jolly-Seber method*—The general Jolly-Seber method is discussed in detail by Seber (1982: chapter 5). In this form the method utilizes repeated releases of newly tagged individuals, along with those animals caught on the $i$th capture occasion that had been tagged previously. Seber denotes these releases of previously and newly tagged animals as $R_i$, while previously tagged animals caught on the $i$th occasion are denoted as $m_i$. Inasmuch as there was no tagging after the first release of a tagged cohort in the present context, we have $R_i = m_i$. Two other quantities needed here are $r_i$, the number of tagged individuals caught later of those ($R_i$) released on the $i$th occasion, and $z_i$, the number of individuals tagged before the $i$th sampling occasion and caught after that occasion but not caught on the $i$th occasion. With this notation, the estimate of survival from occasion $i$ to occasion $i + 1$ (Seber 1982: equation 5.9) becomes:

$$\hat{\Phi}_i = \frac{m_{i+1}\left(\frac{z_{i+1}}{r_{i+1}} + 1\right)}{m_i\left(\frac{z_i}{r_i} + 1\right)}. \tag{6}$$

Because a very high fraction of tagged animals are seen each year, the $z_i$ are frequently zero (or very small), so the survival estimates by this equation reduce largely to the ratio of tagged individuals resighted in two successive years. With relatively small samples such ratios will be highly variable so Equation 6 is only used for the largest samples here. However, the Jolly-Seber calculations were conducted on data from all sites other than Kure, to provide estimates of the probability of sighting to check on the bias in estimating first-year survival described by Pollock *et al.* (1990).

*Variance of survival estimates*—Because the present application of the method of Haldane (1955) is based on repeated observations of the same individuals, it seemed worthwhile to check the variance estimate of Equation 5. This was done with a monte carlo simulation with 30 tagged seals in each of 6 cohorts, survival of 0.90, annual sighting probability of 0.95, and runs of 1,000 simulations. The outcomes gave survival estimates very close to 0.90, but 95% confidence limits were appreciably too wide ("coverage" of about 99.9%) while percentile confidence limits from bootstrapping (Efron and Gong 1983) in the simulations were close to 95%. Consequently, bootstrapping confidence limits (B.C.L.) are given here for all estimates, with the exception of data from Kure Atoll, where convergence problems in the bootstrapping led to use of Equation 5.

## RESULTS

A summary of the tagging and resighting data appears in Table 1, and the analyses are discussed by individual sites below:

*Kure Atoll*—Kure sample sizes are small, but survival rates were 100% for tagged cohorts over long time periods (Table 1), and only in two instances was a tagged individual not seen in one year, then seen later. Using the ratio of one-year-olds to those tagged as weaned pups from 1981 through 1987 gave a first-year survival of 28/32 = 0.88. Pooling all of the Kure Atoll sighting data from the first resighting onwards gave an overall survival rate Equation 4 of 0.98 (0.03). The standard error from Equation 5 is given in parentheses after the estimate. Clearly, the main losses observed at Kure Atoll were in the first year after tagging. The Kure Atoll data in Table 1 are from Kure-born seals only. However, rehabilitated yearlings placed at Kure have also shown good survival after release.

*Pearl and Hermes Reef*—This site is difficult to survey adequately for tag resightings because the atoll contains many small islets scattered along the fringing reef on which monk seals haul out and can be easily disturbed by an observer.

*Table 1.* Resighting data for Hawaiian monk seals tagged as weaned pups on major sites. KUR = Kure Atoll, PHR = Pearl and Hermes Reef, LIS = Lisianski, LAY = Laysan, and FFS = French Frigate Shoals. The tag resighting effort was low in some years.[a] Some undersized weaned pups were removed from the population for rehabilitation and eventual release or for permanent captivity.[b] The table excludes survival data from these seals, however, the total number tagged, including these seals, is shown in parentheses.

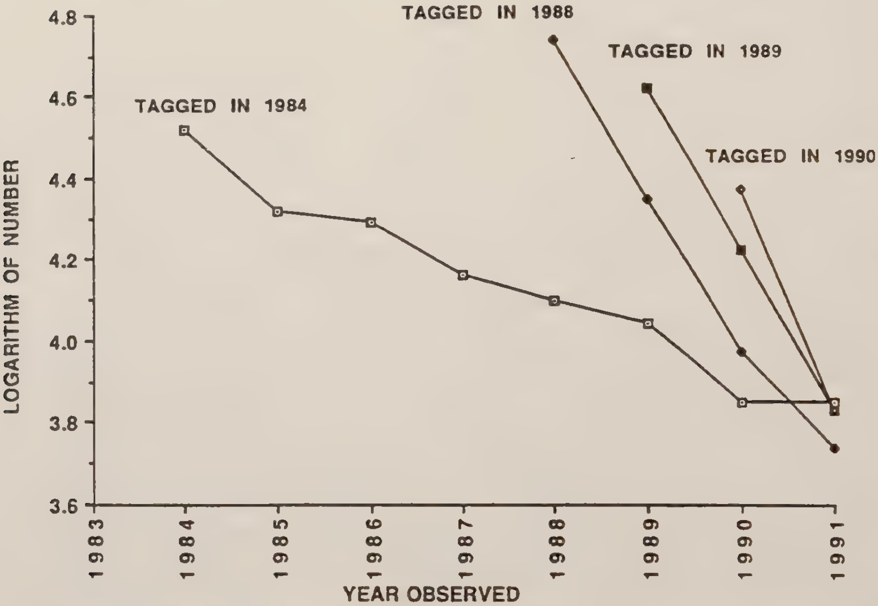

*Figure 2.* Logarithms of resightings of tagged seals at French Frigate Shoals. First points in each series are number tagged.

Most of the births occurred on the two northernmost islands (Westlake and Gilmartin 1990). Only a short duration field camp was possible in 1990, so that the number of resightings dropped sharply in that year. However, the number of sightings rose again in 1991, indicating that survival remained high (Table 1). When another year or two of data have been collected, adjustments of the type utilized in Equation 6 may serve to permit utilization of the 1990 data. However, for the present, we have used regression calculations (Equation 2) for cohorts tagged in 1983 through 1987 to estimate survival beyond the first year. First-year survival was estimated as the ratio of the total seals known to be alive one year after tagging to the total tagged for the years 1983 through 1987, or 62/77 = 0.80 (this calculation involves "back-correcting" two individuals not observed in the first year after tagging but seen in later years). Survival from the regression calculations was: 1983, 0.98; 1984, 0.93; 1985, 0.99; 1986, 0.94 and 1987, 0.93. For pooled survival data through 1989, Equation 4 gave a survival rate of 0.94 (95% B.C.L.: 0.88 to 0.98).

*Lisianski Island*—Only a short field camp was established on Lisianski Island in 1988 and resightings in that year dropped rather sharply. Also, no field camp was present at Lisianski Island in 1989. However, of the 18 weaned pups tagged in 1988, 15 were seen in 1991, and 13 in 1992. Survival calculations by the regression method for cohorts of weaned pups tagged in 1983 through 1986 gave: 1983, 0.92; 1984, 0.90; 1985, 0.77 and 1986, 0.90. First-year survival using back-corrected data for 1982 through 1987 was 88/104 = 0.85.

*Laysan Island*—Annual field camps of long duration that have included pup

*Table 2.* Survival estimate by the Chapman-Robson estimator for monk seals tagged at weaning on French Frigate Shoals. First-year survival not included.

| Year tagged | Survival | | |
|---|---|---|---|
| | Female | Male | Combined |
| 1984 | 0.94 | 0.91 | 0.93 |
| 1985 | 0.93 | 0.89 | 0.91 |
| 1986 | 0.90 | 0.86 | 0.88 |
| 1987 | 0.91 | 0.90 | 0.91 |

tagging have been maintained on Laysan Island since 1983. First-year survival using back-corrected data for 1983 through 1987 gave 119/139 = 0.86 (only one individual was not seen in the first year, but subsequently observed). Inasmuch as field camps were present on Laysan Island in all recent years, an overall estimate by Equation 4 was calculated as 0.85 (95% B.C.L.: 0.81 to 0.88) from the cohorts tagged from 1983 through 1989. Separate estimates for males and females gave 0.82 (95% B.C.L.: 0.73 to 0.86) and 0.87 (95% B.C.L.: 0.81 to 0.91), respectively. Using resightings through 1988 of the first 4 cohorts tagged (1983 through 1986) gives an estimate of 0.89 (95% B.C.L.: 0.84 to 0.94) for males and females combined.

*French Frigate Shoals*—This large atoll is geographically similar to Pearl and Hermes Reef in that the seals use a substantial number of islands, some of small size and difficult to access, making a difficult task of detecting seal tag numbers. However, resighting effort here is much greater due to annual field camp presence of 4–6 mo.

Back-corrected first-year survival from 1984 through 1987 was 344/383 = 0.90, somewhat higher than on any of the the other sites. However, first-year survival has appeared to drop sharply in recent years, along with the appearance of sizable numbers of pups and immature seals in poor physical condition. Survival of tagged seals over all tagged cohorts also appears to have declined since 1988 or 1989. This sharp decline in recent survival is very evident in comparison with the numbers sighted from seals tagged in 1984 (Fig. 2).

The larger samples at French Frigate Shoals (Table 1) make it feasible to consider separate survival estimates for males and females. Female survival was somewhat higher than that of males based on use of Equation 2 to calculate the estimates given in Table 2. Only resightings through 1989 were used in this calculation, due to the evidence of a drop-off in survival beginning in 1989 (Fig. 2). Pooling data through 1989 from cohorts tagged from 1984 through 1987 gave a survival estimate using Equation 4 for females of 0.93 (95% B.C.L.: 0.90 to 0.96) and 0.90 (95% B.C.L.: 0.86 to 0.93) for males. The estimates given thus far used all or part of the successive resightings to estimate survival for a cohort of seals tagged in a given year. This pooling was necessary due to the small samples available. With the larger samples from French Frigate Shoals, it was possible to examine estimates for individual years. For females tagged from 1984 through 1986, the results suggest a higher survival rate for seals born in the first years of the study (Table 3).

*Table 3.* Annual survival estimates for female monk seals tagged at weaning on French Frigate Shoals using the Jolly-Seber estimator.

| Year tagged | Year of estimate | | | |
|---|---|---|---|---|
| | 1984–1985 | 1985–1986 | 1986–1987 | 1987–1988 |
| 1984 | 0.90 | 1.00 | 0.95 | 0.88 |
| 1985 | | 0.97 | 0.94 | 0.98 |
| 1986 | | | 1.00 | 0.94 |

## Discussion

In assessing the results given here, it is important to note that nearly all of the seals in a cohort of weaned pups were tagged in most years, so that the overall survival of a given cohort is recorded by subsequent resighting data (apart from those relatively few cases where a tagged seal was not seen in one year, but was seen subsequently). In many reports of survival calculations, data on a sample of a much larger population are reported. Standard errors may then largely reflect variability introduced by using samples to estimate survival rates. In the present example similar variability results, but the fluctuations are due almost exclusively to chance processes governing whether individual seals lived or died, because all or nearly all seals in a given year-class were tagged.

Discussions of the observed variability are thus not so much concerned with "reliability" of the data as they are with what might have happened to the population by chance; *i.e.*, to some hypothetical population of seals living under identical circumstances to the cohorts actually observed. Because the major purpose of the overall study is to assess the threats to monk seal survival and seek methods for restoration of this endangered population, we need to base decisions on the observed results, and thus have not given much emphasis to variance estimates here.

The monk seal population at Kure Atoll declined severely during the 1960–1970s due to human occupation of Green Island and associated disturbance of pupping beaches (Kenyon 1972). In 1981 a program was initiated to rebuild that population (Gerrodette and Gilmartin 1990), and it appears to have been successful (VanToorenburg *et al.* 1993). With a reduction in human disturbance, the primary birth site has returned to its original location on Green Island (Gerrodette and Gilmartin 1990, Westlake and Gilmartin 1990). The very high survival rates at Kure Atoll suggest that a monk seal population with ample resources can do very well indeed. As is most evident at Kure Atoll, but also apparent at the other sites, and is common in most species of large mammals, first-year survival is lower than that observed in subsequent years.

Survival at Pearl and Hermes Reef, while not as high as at Kure Atoll, is nonetheless adequate to allow population growth, as confirmed by the fact that an initial small population has been increasing steadily over the years of the study (NMFS, unpublished data). Overall survival rates at Laysan and Lisianski Islands seem likely to be generally similar, and appreciably lower than at the other sites. Populations at both islands are not increasing and may be decreasing, a result that we believe is associated with the "mobbing" phenomenon, in which an excess of adult males has caused numerous injuries and outright deaths of adult females in breeding attempts (Hiruki *et al.* 1993). The high survival (0.95) for the first few years at Lisianski Island may well be a consequence of the fact that the younger seals are less affected by the "mobbing" phenomenon, which is mainly noted as individuals approach the breeding age of 5–7 years (NMFS, unpublished data). With the prospect that survival may be lower as individuals, especially females, approach the breeding age, the simple model used here becomes of uncertain utility. Unfortunately, the small sample sizes available make it unlikely that more complex models or statistical tests may be of much help in analysis of the survival data alone. Combining survival, reproductive, and trend count data will be required to clarify the situation at Laysan and Lisianski Islands.

The main pupping site at French Frigate Shoals is East Island (Westlake and Gilmartin 1990) which was the site of military occupation from 1944 to 1952. After abandonment of the site by the U.S. Coast Guard in 1952, pup production at French Frigate Shoals increased substantially (Gerrodette and Gilmartin 1990) and the monk seal population built up rapidly, leveling off in the mid-1980s (NMFS, unpublished data). This population differs in this respect from all of the other sites in that it was small in the late 1950s, when all of the other populations were large, then it increased very substantially, reaching an asymptote in the late 1980s. First-year survival of 0.90 from 1984 through 1987 was a little higher than any other site. The recent dramatic change in immature survival at French Frigate Shoals (apparent in the resighting data since 1989) and other population data suggest this continuing decline is the result of environmental factors affecting food availability, but interpretation is complicated by possible losses of seals in a longline fishery for swordfish in 1990.

Research on the monk seal populations is being continued and intensified. As better understanding of the data and the dynamics of the populations evolves, we believe that more detailed models can be developed for specific analytical purposes.

## ACKNOWLEDGMENTS

Thanks to all members of the Hawaiian monk seal field research teams who tagged the pups and collected the resighting data during the years of this research. We also thank D. DeMaster, L. Hiruki, W. Testa, and T. Ragen for comments on the manuscript.

**Abstract.**–Field and laboratory procedures were used to acquire dolphin school size estimates from vertical aerial photographs. Multiple photographs were taken of 48 separate schools during a 1989 eastern tropical Pacific (ETP) dolphin abundance survey. During a 12-week "counting period," three readers did independent counts of dolphins in the photographs. For each school, the best photograph imagery was selected and the mean of the three independent counts was used to estimate its "true" size. The coefficient of variation (CV) for school size estimates (between-reader precision) averaged 5.4% and ranged between 1.2% and 14.6%. Most (92%) of the schools were estimated with precision, resulting in a CV of less than 9.0%. Within-reader CV averaged 3.5% and ranged 1.4%–7.1%, indicating that readers were quite precise. To test if reader methods were constant during the counting period, temporal trends in estimates were tested by linear regression analyses and a repeated-counts experiment with repeated measures analysis of variance (RM-ANOVA). Regression analyses indicated no significant temporal trends or bias in the deviation of counts from the means. The RM-ANOVA showed a significant "reader with time" interaction which was attributed to the relatively high variability between readers in counts made at the start of the experiment. Results suggested that methods were constant and counts were precise after an initial "warm-up" counting session.

# Method and precision in estimation of dolphin school size with vertical aerial photography

**James W. Gilpatrick, Jr.**

Southwest Fisheries Science Center
National Marine Fisheries Service, NOAA
8604 La Jolla Shores Drive, La Jolla, CA 92038

Visual estimation of the number of dolphins in a school is difficult because dolphins dive and the entire school is rarely visible at the sea surface at one time. Shipboard observer estimates can be highly variable and they may be biased (Scott et al., 1985; Anganuzzi and Buckland, 1989). Consequently, estimates of dolphin population abundance derived from visual survey data may be biased, and resulting management decisions aimed at conserving these populations may be inappropriate.

The Southwest Fisheries Science Center (SWFSC) has been conducting surveys to monitor temporal trends in the abundance of eastern tropical Pacific (ETP) populations of the pantropical spotted dolphin (*Stenella attenuata*), spinner dolphin (*S. longirostris*), striped dolphin (*S. coeruleoalba*) and common dolphin (*Delphinus delphis*). These surveys are one part of a multifaceted effort to conserve ETP dolphins subjected to incidental mortality in the international purse-seine fishery for yellowfin tuna, *Thunnus albacares* (Perrin, 1975; Wade and Gerrodette, 1992). Starting in 1987, in response to the problem of potential bias in visual school-size estimates, annual ETP surveys were complemented with aerial photography of dolphin schools. This allowed shipboard-observer estimates to be compared with estimates (of the same schools) taken from counts of dolphins in the photographs.

School size estimates derived from large-format (126-mm) aerial photographs were validated during a 1979 study when five separate schools (size range: 161–396 dolphins) were photographed and then captured in a tuna purse-seine net (Scott et al., 1985). Results showed that dolphin counts from the photographs were not statistically different from counts tallied by hand as dolphins were being released from the net. This suggested that counts from aerial photographs approximated "true" school size.

This report details photographic and counting methods used to derive dolphin[1] school size estimates from large-format vertical aerial photographs. Many of the techniques originated with Scott et al. (1985). The techniques were modified to support the photography and laboratory efforts associated with large-scale ETP dolphin population surveys (i.e., annual surveys of 120 days; covering a 19-million-km$^2$ study area). After a survey in 1989, three readers did independent dolphin counts from approximately 200 dolphin school photographs (multiple photographs were taken for 48 separate schools) over 12 consecutive weeks. For each school, the best photograph imagery was selected (according to criteria described below) and the mean of the three independent counts was used to estimate its true size. The coefficient of variation (CV) was used to characterize the precision (between-

---

[1] For purposes of this paper, "dolphin" refers to dolphins as well as small toothed-whales that are included in the photograph sample.

and within-reader) associated with the school size estimates.

One concern was that during the 12-week "counting period," readers might be inconsistent in the application of criteria (cognitive or physical methods, or both) used for counting. If readers were inconsistent, then this might affect the accuracy and precision of the estimates. A two-step approach was taken to address this concern. First, temporal trends in the deviation of counts from the means (see Sokal and Rohlf, 1981, p. 50) were evaluated by linear regression. This approach assumed that the mean of three reader counts was close to the true school size and that the sample error was normally distributed. If individual reader counts were not normally distributed, then this might indicate reader bias or a change in criteria. Second, readers did repeated-counts (at four time points during the counting period) of a known sample of photographed schools. This was done to evaluate the consistency of individual readers (within-reader precision) and to test the hypothesis that dolphin counts (from the same photographs) done at the beginning, middle, and end of the counting period were independent of temporal effects. If the hypothesis proved true, then this would support the idea that counting criteria were constant throughout the counting period.

## Materials and methods

### At sea

Aerial photographs analyzed in this report were taken with Chicago Aerial Industries KA-62 aerial cameras mounted vertically on a Hughes 500-D helicopter. The helicopter was stationed aboard the National Oceanic and Atmospheric Administration (NOAA) survey ship *David Starr Jordan*. All cameras had forward-motion compensation (to minimize photo image blur from aircraft movement) and a 76.2-mm lens. Large-format (126-mm) Kodak Aerochrome MS 2448 color film was used. In order to minimize the behavioral response (scattering and deep diving) of the dolphin schools to the helicopter, photographs were taken at 244 m (800 ft) altitude. The scale of the photographs at this altitude was 1:3200, the sea surface area in a photograph frame was 366 $m^2$, and a 2-m dolphin measured 0.63 mm on the film. The camera cycle rate was programmed to expose for approximately 80% film image overlap, i.e., 80% of the area photographed in one frame was photographed again in the next successive frame. Successive exposed photograph frames for a school were recorded as a complete "photo-pass." To enhance the probability of photographing an entire school, multiple photo-passes (avg.=5) were made over a school.

### In the laboratory

**Counts** Light tables equipped with dissection microscopes (0.7× to 7× variable objective and 10× widefield oculars) were used to view and count the dolphin images during counting. Dolphins were counted by hand-tally while being plotted with a permanent marker on a clear acetate overlay. The marked overlay, when moved to the image overlap area of adjacent frames and aligned over dolphins that were previously plotted, made it easier to identify those dolphins not yet counted in the photo-pass. The photo-pass was the unit on which school size estimates were based (Scott et al, 1985); each pass was counted independently by three readers.

**Criteria for selecting the "true" school size** For each of the 48 photographed schools, the readers chose (by group consensus) the one photo-pass where the mean of the reader counts was the best estimate of true school size. This decision was based on the precision of the three replicate counts and the reader assigned "quality ratings" for the photo-pass. Ratings reflected how confident the reader was in the accuracy of the count. For each photo-pass, readers independently assigned quality ratings ranging from 1 to 4. A rating of "1" indicated that a photo-pass had "excellent" quality. A rating of "2" indicated that the count was "good" despite the presence of some questionable images (i.e., it was difficult to discern and count dolphins accurately when images were partially obscured by light-glare or when photographic resolution was reduced for deep swimming dolphins because of loss of light with sea depth). A photo-pass was rated "3" or "fair" when more questionable images were encountered, but readers still believed the count was a close approximation of true school size. A photo-pass rated "4" was deemed unusable for size estimation because the reader felt there were too many questionable images and the count was not a reliable estimate of true school size.

One source of between-reader variation in dolphin photograph counts was reader error, where dolphins were missed or counted twice. Variation also occurred because readers differed in their interpretations of whether questionable images were dolphins or merely background water turbulence in the photographs. Based on the premise that "precision leads to accuracy" (Sokal and Rohlf, 1981), for each photo-pass, the CV of the three independent counts was used to monitor the reliability of the school size estimate. For photo-passes where the CV of the counts exceeded 10%, the dolphin school was re-counted (independently) to see if the precision of the estimate could be improved. If the CV was above 15% after a second count, the photo-pass was excluded from the study because the counts were considered too variable and little confidence was placed in the accuracy of the estimate.

**Analytical methods** The CV was plotted against the variables "school size" and "quality rating" to evaluate how different school sizes and photograph image qualities affected precision. The CV was also used to characterize the precision of individual readers in repeated-counts as described below.

The percent deviation (PD) is a measure of how distant (+ or −) a count is from the mean. Because this difference is expressed as a percentage of the mean, the PD is a consistent index of deviation relative to changes in the mean. For the PD, let $x_{ij}$ be the $i$th reader's determination of the size of school $j$. The average determination (or mean) over three readers of the size of the $j$th school was given by

$$\bar{x}_{.j} = \frac{1}{3}\sum_{i=1}^{3} x_{ij} \ . \qquad (1)$$

The PD of $x_{ij}$ is expressed as

$$PD_{ij} = \frac{x_{ij} - \bar{x}_{.j}}{\bar{x}_{.j}} * 100 \ . \qquad (2)$$

PD values were plotted to evaluate whether individual reader counts were normally distributed or readers were biased (i.e., tended to count high or low relative to the mean). To test for temporal trends in individual reader counts, PD values were regressed against the variable "time." Time represented the chronological sequence, unique for each reader, in which the 48 schools were counted. Logistically, it was impractical for readers to follow the same sequence in working with the photo-passes.

For the repeated-counts experiment, a known sample of six photographed dolphin schools (henceforth referred to as the "experiment schools"), which varied in school size and image quality, were counted four times. Counts were done once at the start of the counting period, then again every 25 days during the period. Changes with time (temporal trends) due to the variables of "school size," "image quality," and "reader" were tested by using a repeated measures analysis of variance (RM-ANOVA) model from Winer (1971; p. 337).[2] Outlier counts were identified by using Shapiro-Wilk's test for normality at $\alpha = 0.05$ (Shapiro and Wilk, 1965). After log-transformation, data met $F$-test requirements of homoscedasticity according to Levene's test at $\alpha = 0.05$ (computer program BMDP7D used, Dixon et al. 1988). The RM-ANOVA was computed using the software program SuperANOVA (Abacus Concepts, 1990).

## Results and discussion

Scott et al. (1985) reported that dolphin school size estimates derived from aerial photographs were accurate and more precise than visual estimates. They found the standard deviation of estimates (log-transformed) averaged 6% of school size for photographic estimates and 10%–30% of school size for visual estimates. The CV for estimates (untransformed) of the 11 schools used in their precision analysis averaged 8.4% (range: 3.7%–15.1%) indicating slightly less precision when compared with estimates presented here (avg. CV: 5.4%; range: 1.2%–14.6%; Table 1). The difference is explained, in part, by their statistical model, which accounted for variance due not only to independent repetitive counts (2 to 4 per photo-pass), but also due to camera types (126- and 229-mm formats) and multiple photo-passes (2 to 7) for a given school. In the present study, variability was minimized by use of one type of camera (126-mm format) and by including only counts of the single best photo-pass for a school.

School size estimates averaged 146 and ranged between 4 and 633 (Table 1). Most schools (92%) were estimated with precision that resulted in a CV of less than 9.0%, and precision varied little with school size (Fig. 1 and Table 2). Estimate precision tended to decrease with decreased quality of the dolphin school photographs (Fig. 2). PD values (listed in Table 1) plotted for individual readers appeared normally distributed, indicating no between-reader bias in counts of the dolphin images.

Repeated-count data are presented in Table 3. Outlier values for experiment school number III (Table 3) resulted from reader error when dolphins were missed as the marked acetate was moved from the dolphin low density area of the photo-pass (in this case, the beginning of the photo-pass) to the high density area. Alternatively, when dolphins in the high density area were counted first, the precision of the estimate was improved because the majority of dolphins in the school were plotted and counted at the onset; this made it easier to track individual dolphins on adjoining frames.

Within-reader CV for repeated counts averaged 3.5%. Reader 2, the most experienced reader, was most precise in repeated counts (avg. CV: 2.6%; range: 1.4–3.8%) followed by reader 3 (avg. CV: 3.4%, range: 1.5–5.1%), and Reader 1 (avg. CV: 4.7%, range: 2.5–7.1%). The RM-ANOVA showed significant differences between

levels of the factors "school size" and "quality rating" (see between-factors; Table 4). This was expected because photographed schools of different sizes were intentionally selected for the analysis. Often, with RM-ANOVA, between-factor effects are confounded with different levels of the factors (as is true for the two factors above) and it is the temporal trends of the within-factor data that are of primary interest in the analysis (Winer, 1971, p. 299). There were no differences between readers in the overall means of their repeated counts (temporal trends not considered; $P$=0.7898; Table 4).

The $F$ value for the within factor "Time" indicated no significant linear trend for repeated-counts (with the mean of the three reader counts). However, a significant interaction for "reader with time" ($F$=3.503; $P$=0.0258; df=6, 31) indicated there were differences between readers in the respective temporal trends of their repeated-counts (Fig. 3). To investigate the source of the significant effect, the trend data for each reader were tested *a posteriori* by contrasts among means with linear coefficients to weigh the log-transformed data (Sokal and Rohlf, 1981; Abacus Concepts, 1990). Results showed the mean of Reader 1's counts at time one differed significantly from the means of counts made at times two, three, and four ($F$=14.977; $P$=0.0005; df=1). This suggested that Reader 1's counts made at time one were important in causing the significant "reader with time" interaction.

Because the initial counts (at time one) of the experiment schools were done just prior to the start of the 12-week counting period, this suggested that

[1] *P*-value corresponding to degrees of freedom adjustment using the Greenhouse-Geisser (1959) epsilon factor (=0.692) to correct for correlation of repeated measures. See Anderson (1958); Barcikowski and Robey (1984); Dunn and Clark (1987).

between-reader variance may have been atypically high early in the counting period as well. The regression analyses of PD values with time, however, did not provide strong evidence for this because reader counts were close to the mean values and no significant temporal trends were detected (Fig. 4). Probable cause for the significant effect was that readers were "out of practice" at the start, especially Reader 1. Prior to the

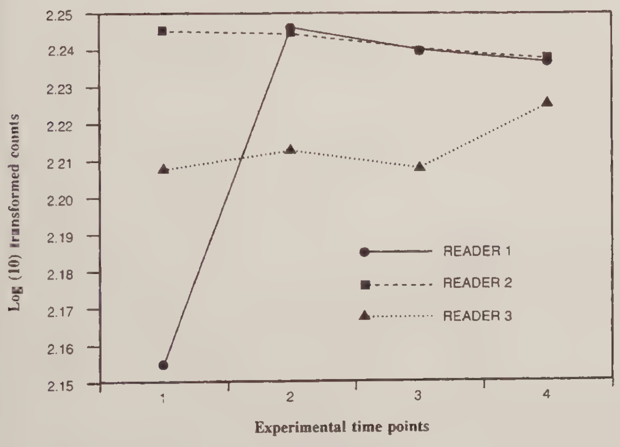

Figure 3

Temporal profiles of the means for counts (log-transformed) made by three independent readers during the repeated-counts experiment.

1991 counting period, a "warm-up" counting session was effective in improving estimate precision, i.e, between-reader CV went from an average of 8% to 4% within one day.

## Conclusion

Results suggest that after a prolonged absence from interpreting dolphin school photographs and doing counts, a warm-up session, where readers are refreshed in counting technique, is important for minimizing reader error and improving precision. Estimate precision is also improved when plotting and counting is initiated at the dolphin high-density area in a photopass. The field and laboratory methods described in this report proved reliable in providing precise dolphin school-size estimates for population abundance studies. The CV statistic and PD index will be used for inter- and intra-annual quality control of dolphin school estimates taken from aerial photographs. The analytical methods used in this paper to describe precision and consistency are applicable to other fisheries and terrestrial wildlife research efforts where independent repetitive counts are conducted for parameter estimation.

## Precious Coral Fisheries of Hawaii and the U.S. Pacific Islands

RICHARD W. GRIGG

*ABSTRACT — The precious coral fishery in Hawaii and the Western Pacific consists of one industry but two distinct and separate fisheries. The first is the harvest of black coral by scuba divers from depths of 30–100 m. The second is a fishery for pink and gold coral at depths between 400 and 1500 m and employs either a human-operated submersible that permits selective harvest or tangle net dredges which are nonselective. The modern history of these fisheries date from 1958 until the present. In this paper the ecology, life history, and management of the dominant species that make up these fisheries are reviewed. Research needs of the fisheries and the economic and future prospects of the precious coral industry are also described. At the present, the precious coral jewelry industry in Hawaii (all species) is valued at about $25 million at the retail level.*

### Introduction

Precious corals have been used by humans for the fabrication of coral jewelry since antiquity (Grigg, 1989). Along with amber, precious coral may have also been used as a source of currency for trade by paleolithic man (Tescione, 1968). As a renewable resource in the sea, precious corals are thought to be the slowest growing organisms of any known fishery past or present. Pink and red coral fisheries exist in the Mediterranean Sea and the Pacific Ocean. Black corals are distributed world-wide and small fisheries for black coral exist in all oceans. Hence, precious corals represent a unique and interesting case history of a fishery which is very old and quite widespread and one which renews itself very slowly. In this paper, these aspects of the fishery are considered but only as they relate to the modern history and management of precious coral fisheries in Hawaii and the Western Pacific during the past 35 years. Over this period in this area, two different precious coral fisheries have been developed; one in relatively shallow water between 30–100 m for several species of black coral, and the other, for pink, gold, and bamboo corals at depths of 400–1500 m. A brief history of both fisheries is presented including a description of their ecology and management of target species. Future research needs for both fisheries are described and future prospects of the precious coral industry are considered.

### Taxonomy

Briefly, all species of precious coral in the Western Pacific belong to one of three Orders within the Class Anthozoa, Phylum Coelenterata. The pink and bamboo corals, *Corallium* spp. and *Lepidisis olapa*, are in the Order Gorgonacea. The Hawaiian gold coral, *Gerardia* sp., is in the Order Zoanthidae and the black corals, *Antipathes dichotoma*, *A. grandis*, *A. ulex*, and *Cirrhipathes anguina*, are all in the Order Antipathidae. Gorgonians are octocorals while the Hawaiian gold and black corals are hexocorals.

### History of the Precious Coral Fishery in Hawaii and the Western Pacific

Commercial beds of black coral were discovered in Hawaii in 1958 by Jack Ackerman and Larry Windley (Stewart, 1962a; Grigg, 1965). This discovery was located 4.8 km due west of Lahaina, Maui, at a depth of 30–75 m along a drop-off known as "stone wall" on the Lahaina Roads Reef. What Ackerman and Windley had discovered were populations of two species of exceedingly large black corals, *Antipathes dichotoma* and *Antipathes grandis* (Fig. 1). Subsequent research has shown that 12 additional species exist in Hawaiian waters but most of these occur at depths below 100 m, and none are large enough or are of sufficient quality to be of commerical value for coral jewelry (Grigg and Opresko, 1977).

The discovery of black coral in Hawaii in 1958 led to the establishment of a small cottage industry that produced curios and black coral jewelry in Lahaina, Maui (Stewart, 1962b). In 1960, John Stewart and Jack Ackerman started a company known as Maui Divers. Over the next ten years, Maui Divers grew steadily under the direction of Clifford Slater, and was joined by about a dozen other small companies. By 1969 the industry collectively was producing about $2 million gross retail sales; part of these sales included imports of pink coral jewelry from Taiwan and Japan.

In 1965, Japanese coral fishermen discovered a huge bed of commercial pink coral at about 400-m depth on the Milwaukee Banks in the Emperor Seamount Chain north of Midway Island near the northwesternmost end of the Hawaiian Archipelago. In terms of significance to the United States, only about 10% of the entire area (the so-called Midway Grounds) exist within the U.S. economic zone (EEZ). Nevertheless, as a result of this discovery, interest in precious coral resources dramatically increased in Hawaii. This stimulated new exploration in the high

Richard W. Grigg is with the Dept. of Oceanography, 1000 Pope Rd., University of Hawaii, Honolulu, Hawaii 96822. Views of opinions expressed or implied are those of the author and do not necessarily reflect the position of the National Marine Fisheries Service, NOAA.

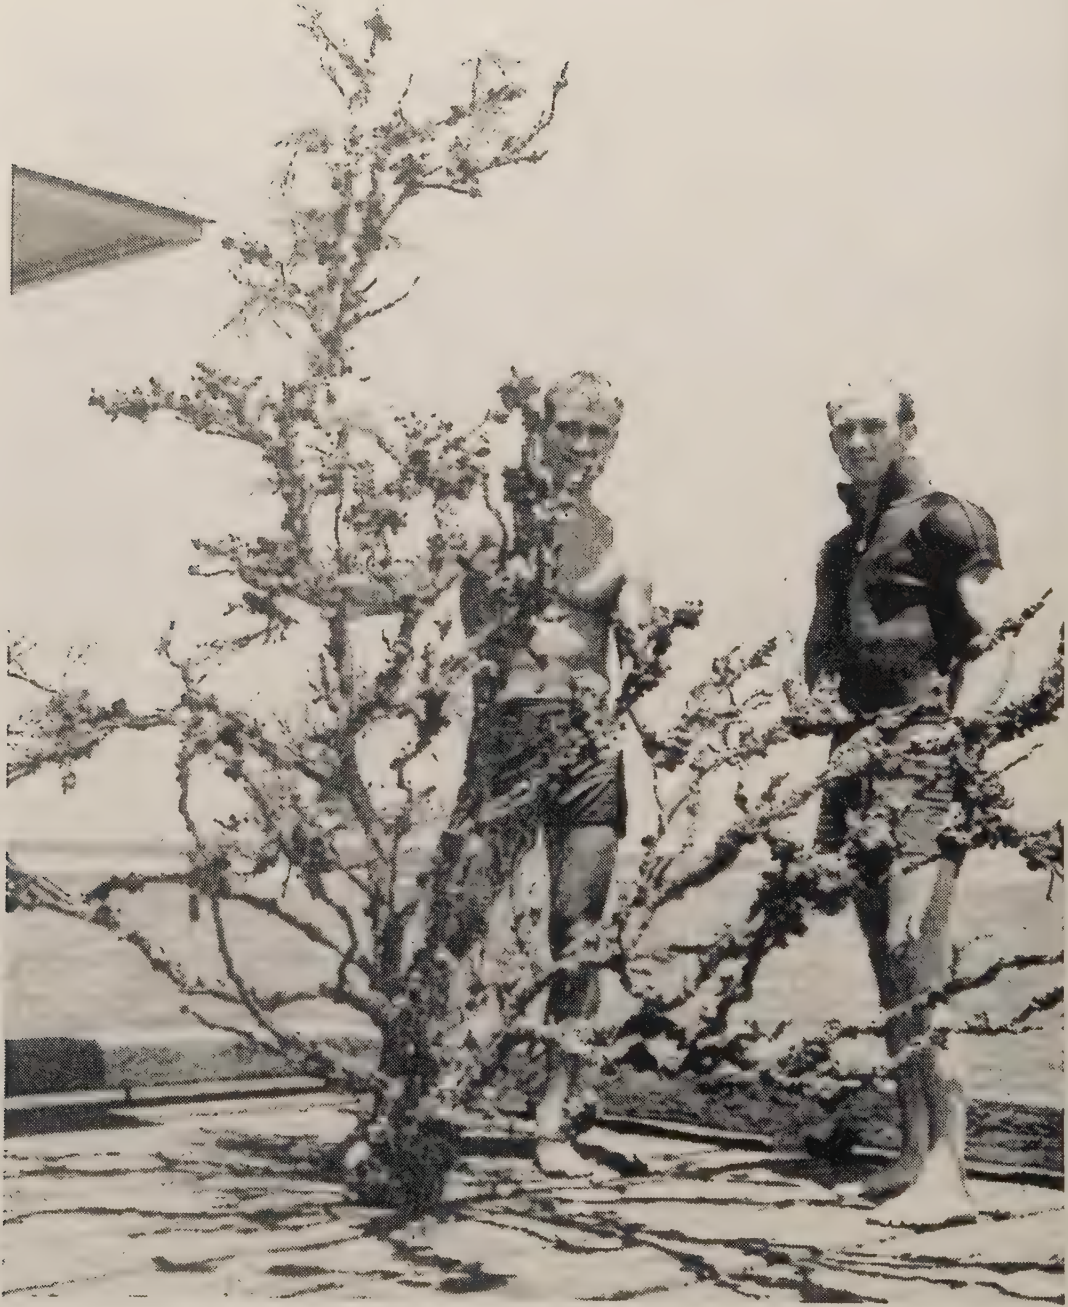

Figure 1.—Jack Ackerman and Larry Windley display a large colony of *Antipathes dichotoma* collected from a depth of 65 m off Lahaina, Maui. The colony is dead and encrusted with numerous sponges and other invertebrates. Even so, the skeleton is still of commercial quality for the manufacture of coral jewelry.

Hawaiian Islands and in 1966, Vernon Brock and Ted Chamberlain of the University of Hawaii discovered a small bed of pink coral *Corallium secundum*, near 400 m depth off Makapuu, Oahu (Fig. 2). In the following three years, a small group of fishermen dredged the Makapuu Bed for pink coral on a small scale using tangle nets (Fig. 3).

In 1970 a long-term research program on precious corals began at the University of Hawaii and this led to the development of a selective harvesting system utilizing a manned submersible (Grigg et al., 1973; Figure 4). In 1973, Maui Divers of Hawaii incorporated this system and began a commerical operation of selective harvest for pink, gold, and bamboo coral which lasted until 1978. The gold coral (*Gerardia* sp.) and bamboo coral (*Lepidisis olapa*) (Muzik, 1978) coexist within the same depth zone and habitat with *Corallium secundum*. The Maui Divers operation lasted 6 years but was discontinued in 1978 because of high operating costs. The annual harvest of pink and gold coral from the Makapuu Bed during this period is given in Table 1. Since this time, the industry in Hawaii has relied on stockpiles of gold coral and exports of pink and red corals (*Corallium* spp.) mostly from Taiwan and Japan. The only other attempt to harvest pink corals domestically within the Western Pacific EEZ was in 1988, when crew members of the vessel *Kilauea* used nonselective tangle nets at Hancock Seamount. Their catch was only 450 kg of *Corallium secundum* and most of the colonies harvested were dead and of low quality.

Because Hawaii's precious coral industry continues to be dependent on sources of raw material outside the US EEZ, it is important to analyze trends in the supply of *Corallium* spp. Pacific-wide. From the time of the major discovery of *Corallium secundum* on the Milwaukee Banks in 1965 to the present, the annual supply of both pink and red corals has been extremely erratic. The harvest of shallow water *Corallium* by Japanese and Taiwanese coral fishermen first peaked in 1969 when production Pacific-wide reached 150 metric tons. Following this boom year, production fell precipitously and remained low for the next five years

**Table 1.—Annual harvest of pink and gold coral from the Makapuu Bed (kg).**

| Year | Gear | *Corallium secundum* | *Gerardia* sp |

(Grigg, 1984). Accurate statistics for these years are not available. Then in 1978, a deep-water undescribed species of *Corallium* (sp. nov.) was discovered by a Japanese fishermen at depths between 900 and 1500 m on the Emperor Seamounts. While the color of this species is spotty (sometimes called Scotch), varing between pink and white, it was extremely abundant, and like the 1965 discovery, it produced a "coral rush." In the peak year of 1981, over 100 coral boats from Japan and Taiwan fished the Midway Grounds and production neared almost 300 metric tons (t) Pacific-wide (Table 2). Unfortunately, this intensive fishing effort led to a gradual depletion of the resource, illustrating the well established pattern for all precious coral fisheries: exploration, discovery, exploitation, and depletion (Grigg, 1989).

By 1991, production Pacific-wide stood at an all time low of 2,930 kg (Table 2) and prices of raw material were at unprecedented highs. According to the American Institute in Taiwan, coral production in Taiwan fell to

1 t in 1990 but exports drawn from previous year stockpiles were 63 t of coral products. As stockpiles of the resource are gradually reduced worldwide, new production will depend on the discovery of new precious coral beds. This boom and bust cycle of harvest and supply dramatically illustrates the need for management of the fishery. Management has been hampered by the multinational character of the fishery and because many precious coral beds exist in international waters.

In contrast to the pink and red coral fishery in the Pacific, the black coral fishery in Hawaii is relatively stable. While demand has fluctuated considerably over the years since its discovery in 1958, the supply of black coral has never failed to meet demand. In the early years of the industry during the 1960's and early 70's, as much as 10,000 kg were harvested annually from the black coral beds off Maui and Kauai. During the late 70's and early 80's the demand for black coral was greatly reduced, being replaced by a higher consumer interest in pink and gold coral. However, since about 1986, demand for black coral has been steadily increasing. Consumption by one company, Maui Divers of Hawaii, Ltd., illustrates this trend (Table 3).

Production by Maui Divers of Hawaii accounts for more than 50% of all locally produced black coral jewelry in the State of Hawaii. Today, considerably less black coral is used for fabrication than during the 60's and 70's because the jewelry items produced are smaller and of higher quality and because modern cutting procedures are much more efficient than in the past. In November of 1987, black coral was named the State "Gem" and this has increased consumer interest considerably.

Over the years, the stability of the industry has been aided by the availability of inexpensive black coral from the Philippines and Tonga (Harper, 1988). These sources have filled the demand for low quality but high volume jewelry products. Also black coral resources in Hawaii have been well managed by local fishermen who voluntarily do not harvest colonies below

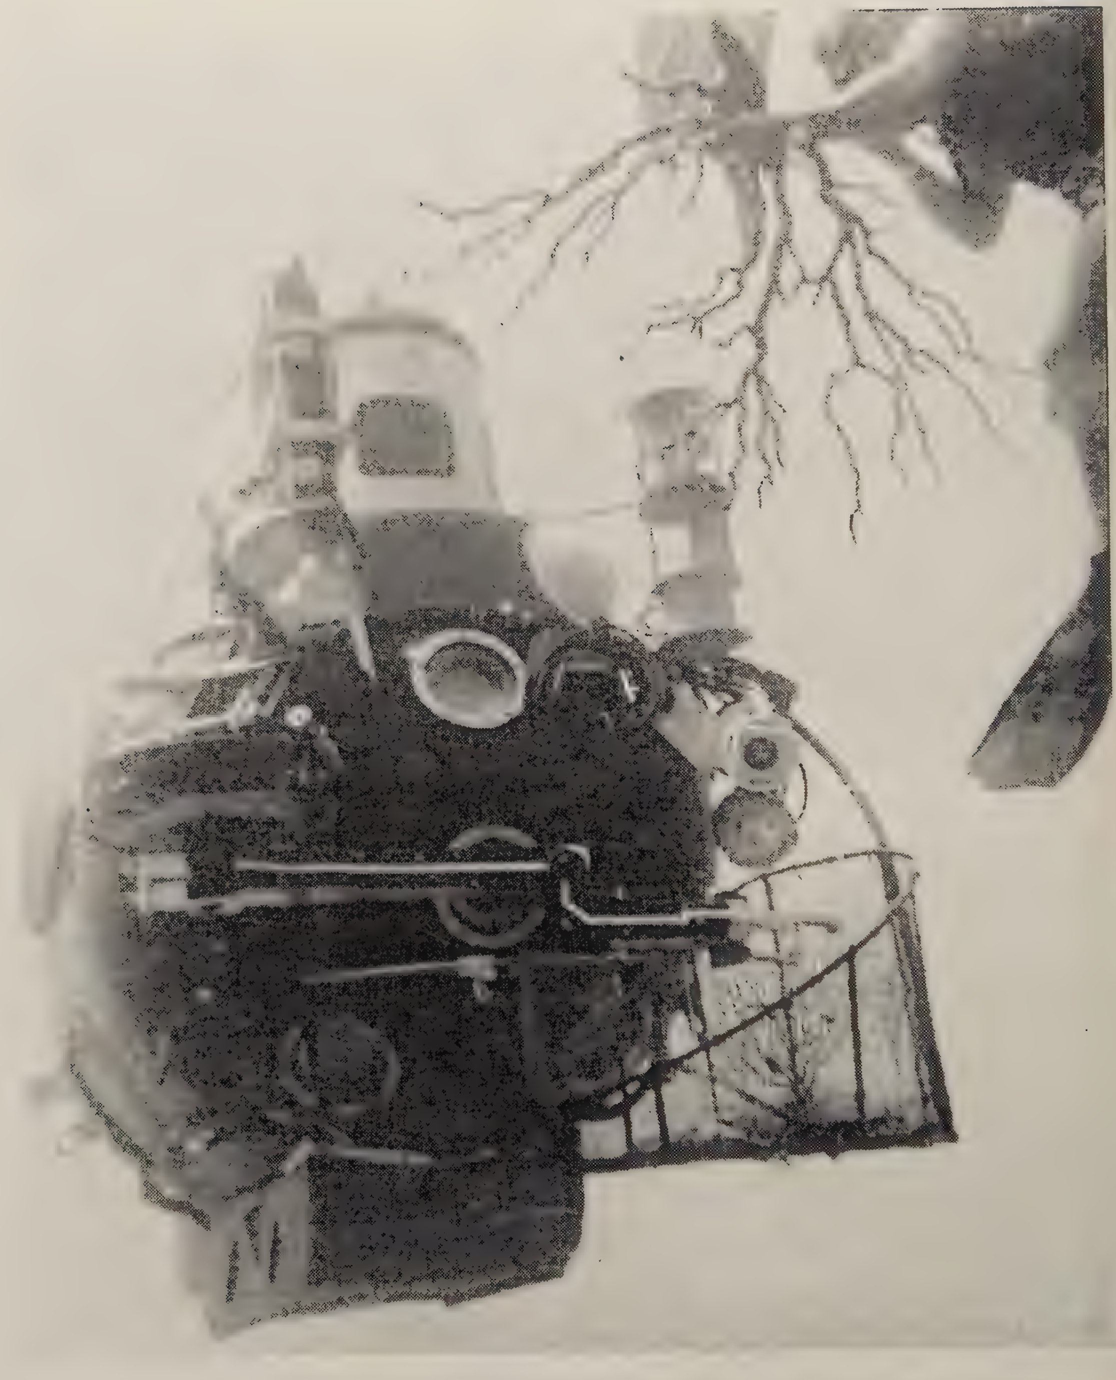

Figure 4.—As the Maui Divers *Star II* submersible approaches the surface, a subtender using scuba collects gold coral, *Gerardia* sp., from the basket.

48 inches (1.2 m) in height. This size limit has been adopted by the Western Pacific Regional Fisheries Management Council and has been recommended to the State of Hawaii and is based on the growth rate and reproductive pattern of *Antipathes dichotoma* and calculations of maximum sustained yield (Grigg, 1976).

Overall, the precious coral industry in Hawaii has steadily grown over the past 34 years since its inception. At the retail level today, the precious coral industry is valued at about $25 million and consists of about 100 retailers.

A small but stable black coral fishery in Hawaii continues to thrive while the fishery Pacific-wide for *Corallium* spp. has drastically declined owing to depletion of the resource. Present demand for *Corallium* is being met largely by the utilization of stockpiles. The future of the *Corallium* fishery will depend on the discovery of new beds of commercial grade species of pink and red coral.

### Ecology of precious corals

The ecology and patterns of life history of various species of precious corals have been reviewed by Grigg (1974, 1976, 1984, 1989). In general, most species of precious corals are slow growing, have low rates of recruitment and mortality, and consequently are relatively long lived. The oldest colonies of *Corallium secundum* in the Makapuu Bed off Oahu probably reach an age of 75 years, and the largest colonies of *Antipathes dichotoma* and *A. grandis* may even be older. Populations of both *Corallium secundum* and both black coral species appear to be recruitment limited (Grigg, 1988). In favorable environments for *Corallium secundum* and *A. dichotoma* in Hawaii, populations are relatively stable suggesting that recruitment and mortality are approximately in steady state. However, in suboptimal environments, the age frequency distributions of both species are very uneven or truncated probably owing to episodic mortality events (personal observation).

Mortality is most often the result of smothering by sediments and by bioerosion of the substrata which leads to toppling of colonies. Fragmentation and reattachment (asexual reproduction) appears to rarely occur. Most species of precious coral are uni-sexual or dioecious, i.e. the sexes are separate. The age of reproductive maturity of *Corallium secundum* and *A. dichotoma* is similar, occurring about age 12–13 which is about one-sixth the longevity of the oldest colonies. Fertilization of Hawaiian precious corals appears to take place externally within the water column. The duration of the larval stage is unknown for most species of precious coral, but studies of one species, *Corallium rubrum*, in the Mediterranean Sea suggest that larvae of this species remain competent for several weeks (Vighi, 1970). In general, settlement is most successful on clean swept surfaces exposed to strong bottom currents. The larvae of both species of *Antipathes* in Hawaii are known to be negatively phototactic which explains why they are not found at shallow depths (< 30 m) and are most abundant beneath overhangs and on other dimly lit surfaces (Grigg, 1965).

The ecological requirements of all species of precious coral in the western Pacific can be briefly summarized as follows. All species require a firm (rocky) substratum free of sediment and most thrive in areas swept by moderate to strong currents. All species lack symbiotic algae in their tissues (ahermatypic) and most are found in deep water below the euphotic zone (Table 4). All species are filter feeders and many are fan-shaped, a growth form which maximizes contact of feeding surfaces with particles or microplankton entrained in the water column. Light and temperature appear to influence larvae more than adults. The lower depth limit of *A. dichotoma* and *A. grandis* coincides with the top of the thermocline in the high Hawaiian islands. Larvae may avoid settling deeper where lower temperature may prevent reproduction (Grigg, 1977, 1984). Species of *Corallium* exist below the euphotic zone at depths between 350 and 1,500 m where temperature varies between 14° and 3°C.

### Resource management

The life history attributes of all species of precious corals in the western Pacific make these living resources highly vulnerable to over-exploitation in unmanaged fisheries. This is because many year classes are exposed to harvesting at the same time. Virtually decades of accumulated standing stock can be collected during short intensive periods of fishing. Indeed, the historical pattern of the fishery worldwide is one of discovery, exploitation and depletion.

Historically, species of *Corallium* have been harvested non-selectively using various types of dredges. In the Meditteranean Sea a heavy wooden cross outfitted with tangle netting (The Cross of Saint Andrew) is dragged across the bottom where corals are broken and entangled in the mesh. Japanese and Taiwanese fishermen also use tangle gear although theirs is simpler in design, consisting of either stones or iron bars with attached netting (Fig. 3). Since the inception of SCUBA, shallow water colonies in the Medit-teranean Sea (up to 110 m in depth) have been harvested selectively by divers. In Hawaii the black coral fishery also employs SCUBA divers who selectively harvest colonies with axes, hammers, and saws (Fig. 4). The first selective harvest of *Corallium* in which a submersible was used by Maui Divers of Hawaii in 1973. This was accomplished with the use of a sophisticated cutter, claw, and basket assembly that was attached to the submersible (Fig. 5, Grigg et al., 1973). Since 1983 an unmanned submersible (robot) has been used in Japan to harvest selective species of precious coral in traditional seas (Table 2).

Precious coral resources in Hawaii and the Western Pacific fall under the

**Table 4.—Depth zonation of all species of precious coral in the western Pacific.**

| Species and common name | Depth range (m) |
|---|---|
| *Corallium secundum*, Angle skin coral | 350–475 |
| *Corallium* sp. nov., Midway deepsea coral | 1000–1500 |
| *Gerardia* sp., Hawaiian gold coral | 300–400 |
| *Lepidisis olapa*, bamboo coral | 350–400 |
| *Antipathes dichotoma*, black coral | 30–100 |
| *Antipathes grandis*, pine black coral | 45–100 |
| *Antipathes ulex*, fern black coral | 40–100 |
| *Antipathes anguina*, wire black coral | 20–60 |

management authority of the State of Hawaii and the U.S. Federal government. The State has clear jurisdiction over resources out to three miles but also claims authority over inter-island waters. Hence the State has declared jurisdiction over the Makapuu Coral Bed situated 9 km (6 miles) off Makapuu in the channel between Oahu and Molokai. Federal jurisdiction extends from 3 miles outside the State of Hawaii, Guam, and American Samoa to 200 miles, and from the shoreline of all U.S. possessions in the Western Pacific (Johnson Atoll, Kingman Reef, and Palmyra, Wake, Jarvis, Howland and Baker islands) to 200 miles. This area is defined as the U.S. Exclusive Economic Zone (EEZ).

Presently black corals in Hawaiian waters are managed by the State of Hawaii. Fishermen are required to have commercial fishing licenses and report their catch monthly to the Hawaii Division of Aquatic Resources. A state regulation has been drafted which sets a minimum size of 48 inches in colony height and 3/4" in basal diameter for the harvest of *A. dichotoma* and *A. grandis*. At the present time, black coral divers in Hawaii comply voluntarily with this draft regulation.

Precious coral resources within the U.S. EEZ (Fig. 6) are managed by the Western Pacific Regional Fishery Management Council (WESTPAC), under a Fishery Management Plan (FMP) for precious coral (Dep. of Commerce, 1980). The FMP, finalized in September 1983, allows for domestic and foreign fishing by regular or experimental permits and requires logbooks of the permittees. Specific regulations contained in the FMP are as follows:

The FMP and regulations outline and classify the known beds of precious corals within the Western Pacific Region, and designate harvesting method and the amount of corals that can be harvested. There are four bed classifications: 1) Established Beds, 2) Conditional Beds, 3) Refugia Beds, and 4) Exploratory Permit Areas. Established beds are ones with a history of harvest, and optimum yields have been established on the basis of biological stock assessment techniques, and selective harvesting gear (submersibles or remote control harvester vehicles) is required. Makapu'u is the only designated Established Bed. Conditional beds are ones for which yields have been estimated on the basis of bed size relative to established beds with the assumption that ecological conditions at established beds are representative of conditions at all other beds. Four beds are designated as conditional beds: Kea-hole Point, Kaena Point, Brooks Banks, and 180 Fathom Bank. Nonselective harvesting is permitted only in the two conditional beds in the Northwest Hawaiian Islands (Brooks and the 180 Fathom Banks). A refugia bed is one set aside to serve as a baseline study area and possibly reproductive reserve. No harvesting of any kind is permitted in Refugia. Presently, the WESTPAC bed, between Nihoa and Necker Islands, is the only designated Refugia. Exploratory permit areas are unexplored portions of the EEZ in which coral beds are almost certain to exist, but no beds have yet been lo-

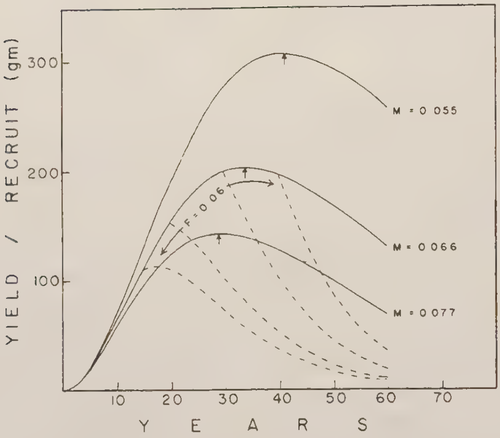

Figure 7.—The Beverton and Holt yield-per-recruit model was used to estimate MSY (vertical arrows) for *Corallium secundum* in the Makapuu coral bed at 3 different values of natural mortality. Dashed lines indicate yield curves produced by applying a fishing mortality of 0.06 at four different ages.

cated. There are four exploratory permit areas; one surrounding the Hawaiian Islands, another that encompasses Guam and the Commonwealth of the Northern Marianas, a third that encircles American Samoa, and a fourth, which was created by Amendment 1 to the FMP, which includes the EEZ's of all the remaining U.S. Pacific Island possessions. Either selective or nonselective harvest gear is permitted in exploratory permit areas except in the Hawaii exploratory area around the Main Hawaiian Islands.

Specific weight quotas and size limits have been determined based on estimates of maximum sustainable yields and optimum yields. For example, the established bed at Makapu'u has a 2-year harvest quota for selective gear only: 2,000 kg for *C. secundum*, 600 kg for *Gerardia* sp. and 500 kg for *L. olapa*. Only colonies of *C. secundum* taller than 10 inches can be harvested. Quotas of 1,000 kg of all species of precious coral combined, exist for each of the EEZ exploratory areas. Foreign fishing is allowed in exploratory areas, if the quotas are not taken by domestic fishermen. Maximum sustainable yields were calculated by using the Beverton and Holt cohort production model (Beverton and Holt, 1957) for *Corallium secundum* (Fig. 2, 7) and the Gulland Model (MSY = 0.4 *M Bo*) where *m* = natural mortality and *Bo* is the virgin biomass, for *Gerardia* and *Lepidisis*.

Having described the management measures established to conserve precious coral resources in Hawaii and the Western Pacific, it is important to evaluate their effectiveness over the history of the fishery. For pink corals, management efforts have been successful for the domestic fishery; however, poaching by foreign fishing has frequently occurred within the U.S. EEZ and is difficult to control.

Considering the domestic coral fisheries first, the cumulative harvest of *Corallium* from the Makapu'u bed between 1966 and 1978 was about 32% of the standing stock. The average annual harvest was 685 kg, somewhat less than the best estimate of MSY, near 1,000 kg. Surveys of the Makapu'u bed in 1983 and again in 1985 showed substantial recovery at rates in close agreement with model predictions in the FMP (Grigg, 1988). For black coral, the combined MSY for beds off Maui and Kauai is 6,250 kg/yr (Grigg, 1976). Harvest levels of black coral above MSY occurred only in the earliest years of the fishery (Table 3) and supply has always been unable to meet demand. Only the most accessible black coral beds off Lahaina, Maui, have been depleted.

Foreign poaching has been a serious problem in the past. During the 1980's, Japanese and Taiwanese coral vessels continuously violated the EEZ near the Hancock Seamounts. In 1985, about 20 Taiwanese coral draggers reportedly poached about 100 tons of *Corallium* from seamounts within the EEZ north of Gardner Pinnacles and Laysan Island. Absence of poaching since that time could indicate that the resources in these areas have been economically exhausted. A research program is currently planned to resurvey the Hancock Seamounts in 1994 with the University of Hawaii research submersible *Pisces V*, in order to assess the present condition of precious coral resources in this area.

## Research Needs and Future Prospects

The most pressing need of the precious coral fishery (and industry) is stock assessment; first in order to describe the status of the stocks within established grounds, and second, to discover new areas. Without substantial efforts to explore and discover new grounds, the precious coral fishery will undoubtedly continue to decline. The problem will become increasingly more serious as existing stockpiles accumulated during the early 1980's are gradually exhausted.

The most promising exploratory areas appear to be in southern oceans. Channel waters around Madagascar and Tasmania (Grigg and Brown, 1991) are particularly promising areas and scattered occurrences of large colonies of *Corallium* spp. have been reported (exact locations are well guarded secrets). Considerable exploration has been conducted in the tropical Pacific by CCOP-SOPAC (Committee for Coordination of Joint Prospecting for Mineral Resources in South Pacific Offshore Areas), and *Corallium* spp. have been recorded from many localities (Cook Islands, Fiji, Kiribati, Solomon Islands, Tonga, Vanuatu, and W. Samoa), but unfortunately not in commercial quality or abundance

(Harper, 1988). Most exploratory dredging by CCOP-SOPAC, however, has been at depths between 200 and 500 m, and virtually nothing is known about the potential of deeper water resources (such as *Corallium* sp. nov. which occurs at a 1,000–1,500 m depth by the Emperor Seamounts).

Another important research question concerns recovery rates (recruitment and growth) in areas which have been heavily harvested. A proposal to assess the stocks on the Hancock Seamounts using the *Pisces V* submersible has been accepted by the Hawaii Undersea Research Laboratory at the University of Hawaii and is presently scheduled for the summer of 1995. The whole area of population dynamics of precious corals is in need of further research.

The mariculture of precious corals is an exciting new area of research. A new laboratory for the biological, economic, and technical research of precious corals has recently been established in Kochi, Japan, in order to attempt the culture of precious coral (Sadao Kosuge, Director of the Institute of Malacology, Tokyo. Personal commun. 1992). To date, colonies of *Corallium japonicum* have been maintained alive in culture for over one year but growth rates are very slow and colonies have not been induced to reproduce. However, the research is still in a very early stage.

While a complete analysis of the economics of the precious coral fishery is beyond the scope of this paper, it is important to mention that this is another area in need of future research. The worldwide glut of *Corallium* precious coral produced during the boom years of the early 1980's caused prices to fall sometimes even below break-even costs for Taiwanese and Japanese coral fishermen and many vessels dropped out of the fishery during this time. The future supply of *Corallium* to the Hawaiian industry will probably continue to depend on exports from these countries; therefore, what happens to the Japanese and Taiwanese fleet is important. Exploration is very expensive and there appears to be little Japanese or Taiwanese interest in wide ranging fishing expeditions at the present time. For this reason, the future of the industry can only be described at this juncture as uncertain. Prices will undoubtedly continue to climb. The raw material for Midway deep-sea coral is still (1990) reasonable at about $150/kg but prices for high quality pink and red *Corallium* peaked in 1990 at $3,069/kg and $16,103/kg, respectively (D. Ancona, U.S. Embassy, Tokyo. Personal commun. 1991). The future of the industry would appear to depend on either successful future exploration or a breakthrough in the mariculture of precious corals.

As for the future of the black coral fishery, at least in Hawaii, it appears to be secure in terms of both supply and demand for the resource. The management of other species of precious coral in Hawaii and the Western Pacific will continue to be covered by the existing FMP of WESTPAC. Regarding the control of foreign fishing in international waters, it is in the best interest of the United States, Japan, and Taiwan to enter into an international treaty for the purpose of conservation of precious corals. However, before this can be achieved, an impetus for such implementation must be initiated by one or all three countries. Based on the principle of common heritage embodied in the International Law of Sea (LOS) convention, and on articles of the LOS Treaty which urge agreements between member countries on measures to conserve living resources within and beyond EEZ's, the Western Pacific Fishery Council has requested that the U.S. State Department enter into multilateral arrangements with Japan and Taiwan for jointly managing the precious coral fisheries in the Pacific.

# Biology and Management of Deepwater Snappers of the Hawaiian Archipelago

WAYNE R. HAIGHT, DONALD R. KOBAYASHI, and KURT E. KAWAMOTO

The authors are with the Honolulu Laboratory, Southwest Fisheries Science Center National Marine Fisheries Service, NOAA, 2570 Dole Street, Honolulu, Hawaii 96822

*ABSTRACT — Commercial and recreational deepwater (100–400 m) bottomfishing in Hawaii targets a multispecies group of lutjanid snappers. Relatively little is known about the life history of these species. Research in Hawaii and elsewhere in the tropical Pacific suggests that most of the species are slow growing, long lived, and have a relatively high age at sexual maturity. Stock assessment is difficult because of the multispecies nature of the fishery. However, recent analysis of commercial fishery data indicates that some of the species may currently be overexploited. Research is underway to determine the efficacy of management measures such as minimum-size limit changes or seasonal and spatial fishery closures to maintain optimal spawning biomass.*

## Introduction

Commercial exploitation of deepwater snappers in Hawaii began before the turn of the century (Cobb, 1903), and except for a hiatus during World War II, has continued to the present. The fishery operates throughout the Hawaiian archipelago, but the inhabited Main Hawaiian Islands (MHI) experience the highest exploitation by both commercial and recreational fishermen. The uninhabited islands and atolls northwest of Niihau, called the Northwestern Hawaiian Islands (NWHI) (Fig. 1), are fished mainly by commercial fishermen.

The deepwater handline fishery targets a multispecies group of fishes consisting of snappers (Lutjanidae), groupers (Serranidae), and jacks (Carangidae). However, snappers are the most important group in the fishery, both by numbers and revenue.[1] Most of the commercially important species have a relatively high age at maturity, long life span, and slow growth rate. These factors, combined with considerable variation in larval recruitment, make these fishes highly susceptible to overfishing. Recent evidence suggests that some of the species may be overfished, and several others are approaching a level of concern[1, 2] (Ralston and Polovina, 1982; Ralston, 1984).

Historically, minimum size limits have been the only measure used to manage both the MHI and NWHI stocks. Since 1989, the NWHI have been managed on a limited entry system. Minimum size limits remain the only management tool currently in effect in the MHI. Several management measures are being evaluated to maintain adequate spawning stock biomass in the future. These include changing minimum size limits, creating closed refuge areas, and imposing bag limits and closed fishing seasons.

This report presents a summary of available information regarding the biology, fishery, and management of these valuable species.

## Species and Distribution

The commercially important deepwater snapper complex in Hawaii is composed of seven species of the lutjanid subfamily Etelinae: *Pristipomoides filamentosus* (opakapaka), *P. seiboldii* (kalekale), *P. zonatus* (gindai), *Etelis carbunculus* (ehu), *E. coruscans* (onaga), *Aprion virescens* (uku), and *Aphareus rutilans* (lehi). Some commercial landings of an introduced snapper, *Lutjanus kasmira* (taape), are also made, but this species usually occurs in shallower water than the other species. The commercially important deepwater lutjanids inhabit the deep slopes of island coasts and banks at depths of 100 to 400 m. These banks and deep slopes comprise an area over 6 times that of shallow water reefs in the state. Biological production in these deepwater areas is thought to be quite different from shallow-water coral reef areas (Agegian et al., 1988).

Throughout their spatial and depth range, deepwater snappers in Hawaii are typically distributed in a clumped pattern, and are often associated with underwater headlands and areas of high relief. Four of the deepwater snapper species found in Hawaii were observed in situ from manned submersibles and an unmanned remotely operated vehicle (ROV) and were found to form large aggregations of up to 100 individuals near submerged promontories and areas of high relief (Brock and Chamberlain, 1968; Ralston et al., 1986; Haight, 1989). This clumped distribution pattern is also apparent when fishing from the surface.

A contributing factor in the distribution pattern of these fish may be that

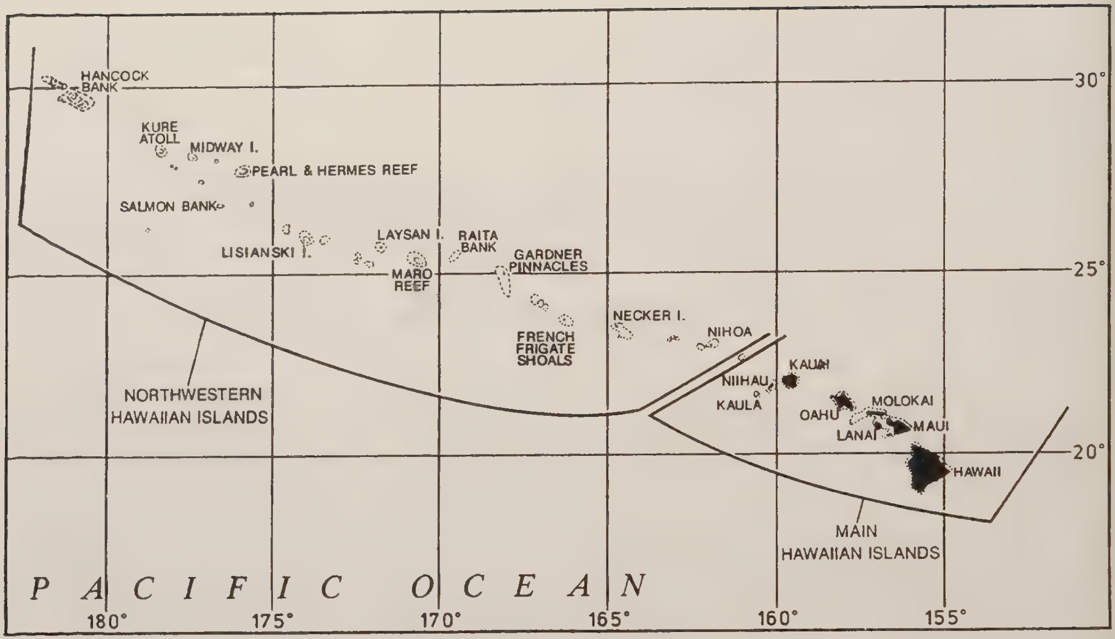

Figure 1. — The Hawaiian Archipelago

currents striking deepwater areas of high relief form localized zones of turbulent vertical water movement, increasing the availability of planktonic prey items (e.g. Brock and Chamberlain, 1968). In an ecological study of the bottomfish resources of Johnston Atoll, Ralston et al. (1986) found *P. filamentosus* in much higher densities on the upcurrent versus the downcurrent side of the atoll, and postulated that this was related to increased availability of allochthonous planktonic prey in the neritic upcurrent areas due to oceanic currents impacting the atoll. Although snappers throughout the world are generally thought of as top level carnivores, several snapper species in the Pacific are known to incorporate significant amounts of zooplankton, often gelatinous urochordates, in their diets (Parrish, 1987). Haight et al. (1993) found zooplankton to be an important prey item in four of the commercially important snappers in Hawaii. The same study found that the six snapper species studied were either primarily zooplanktivorous or primarily piscivorous and showed little overlap in diet composition between trophic guilds.

## Reproduction

Relatively little is known about the reproduction and early life history of deepwater snappers in Hawaii. Size at maturity has been estimated for only two species in the MHI and two species in the NWHI. In the MHI, uku reaches sexual maturity at 47 cm fork length (FL), which is 46% of maximum size ($L\infty$). Onaga reaches sexual maturity at 61 cm FL (62% $L\infty$) (Everson et al., 1989). In the NWHI, ehu reaches maturity at about 30 cm FL (46% $L\infty$) and opakapaka reaches maturity at around 43 cm FL (48% $L\infty$) (Everson, 1984; Kikkawa, 1984; Grimes, 1987).

There is a record of one anecdotal observation on the spawning behavior of opakapaka in Hawaii. A NWHI commercial fisherman using a chromoscope depth sounder observed an opakapaka aggregation at about 150 m become very dense during the mid-morning hours. Catch rates decreased at this time, and egg masses were observed adhering to the fishing gear. By mid-afternoon the school became less compacted and catch rates increased. Opakapaka caught during this time were in spawning condition, some females released eggs and males released milt. Free-floating eggs were noted covering a large surface area around the vessel. The observations were made in mid-April.[3]

Gonadal studies on four of the species in Hawaii indicate that spawning may occur serially over a protracted period but is at a maximum during the summer months, and peaks from July to September (Everson et al., 1989; Uchida and Uchiyama, 1986). Estimated annual fecundity is 0.5 to 1.5 million eggs. The eggs are relatively small (0.7 to 0.8 mm) and are released into the water column.

### Larval and Juvenile Stages

Newly hatched larvae of lutjanids in general are typical of those from fish with small pelagic eggs; the larvae have a large yolk sac, unpigmented eyes, and no mouth. The yolk sac typically lasts 3–4 days, after which the mouth is fully formed and the eyes become pigmented (Leis, 1987). The larval stages of snappers in Hawaii are poorly studied, perhaps because of their rarity in plankton samples. In a 16–month survey of the larval fishes near Oahu, snappers of the subfamily Etelinae were taken exclusively in the late summer and fall, and occurred in very low numbers, making up less than 0.5% of the 5,200 fish larvae identified (Clarke, 1991). Snapper larvae are thought to be planktonic and subject to advection by ocean current systems until benthic habitat suitable for metamorphosis is encountered (Munro, 1987). The duration of the pelagic phase is thought to be at least 25 days (Leis, 1987).

Little information currently exists on larval development, settlement, or early juvenile life history of deepwater snappers in Hawaii. Despite considerable research effort directed toward snapper productive processes in Hawaii, little is known about the ecology of juveniles from time of settlement to their appearance in the adult fishery. Age at entry to the fishery for the principal species is thought to be 2 to 3 years after settlement.[4] In a three-year study of fish settlement on artificial reefs adjacent to adult snapper habitat in Hawaii, no recruitment of juvenile snappers to the reefs was observed, although adults aggregated at times around the reef structures (Moffitt et al., 1989).

Occasional reports of recreational fishermen taking juvenile opakapaka while fishing in depths less than 100 m prompted exploratory research fishing to be conducted in these nearshore areas. Results from a 13–month intensive fishing program off Kaneohe Bay, Oahu, Hawaii indicated juvenile opakapaka first appear in the relatively shallow (60–100 m) nearshore areas at about 10 months of age (7–10 cm FL) during the fall and early winter months. The young opakapaka remain in this habitat for the next 7 months until they reach 18–24 cm FL.[5] In situ scuba observations of the juvenile habitat found it to be a relatively flat, soft sediment substrate devoid of relief (Parrish, 1989). Recent trawl surveys suggest juvenile opakapaka are fairly widespread throughout the MHI in similar habitat and depths.[6]

### Age, Growth, and Mortality

Tropical snappers in general are slow growing, long lived, and have low rates of natural mortality. Maximum ages exceed 10 years, and von Bertalanffy growth coefficients ($K$) are usually in the range of 0.10 to 0.25 per year (Manooch, 1987). Most aging studies of tropical snappers have depended on the enumeration of regularly formed marks on calcareous structures. The extended reproductive cycles and weakly expressed seasonality of growth in these fishes, however, confounds the accuracy of such studies. In Hawaii, Ralston and Miyamoto (1983) used daily growth increments deposited on the otoliths of immature *P. filamentosus* to determine its growth rate. Using in vivo tetracycline injection as a validation technique, they concluded that daily otolith increments were deposited in fish up to 3 years old (sexually mature), however, aging of fish greater than age 3 was difficult owing to episodic otolith deposition in sexually mature fish. Based on the growth of immature fish, the estimated growth coefficient of opakapaka was 0.145 per year, and asymptotic upper boundary on growth ($L_\infty$) was 78 cm FL, which occurred at over 18 years of age.

Ralston (1987), in a comprehensive review of published reports on snapper growth and natural mortality, determined that for the 10 species studied, mortality and growth rates were highly correlated, with a mean $M/K$ ratio of 2.0. Thus, if a value of $K$ is available for a given species, its natural mortality rate can be estimated. Using an age-length probability matrix for opakapaka applied to length frequency samples, Ralston (1981) estimated the natural mortality rate for opakapaka in Hawaii to be 0.25, which when compared to the estimated $K$ value for this species (0.145) is close to the value predicted by the $M/K$ relationship derived for snappers in general.

### Fishery Synopsis

Deepwater snapper in Hawaii have been commercially exploited since the early part of the century. In 1925, the Territorial Legislature, concerned with an increasing level of fishing pressure, imposed a one-pound minimum size limit for most of the deepwater snappers. By the 1930's, a fleet of vessels fished for bottomfish throughout the archipelago, with as many as five large (20 m) vessels venturing into the NWHI. After the hiatus imposed on the fishery by WWII, as many as nine vessels fished the NWHI. Landings peaked in the early 1950's at about 500 t, and declined steadily through the mid-1970's (Fig. 2). In the mid-1950's, poor fish prices and vessel losses reduced the number of fishermen in the NWHI; by the 1960's only one vessel remained in operation in the NWHI (Hau, 1984). There was renewed interest in the resources of the NWHI in the mid-1970's when state and federal agencies collaborated in a study focusing on the resources of this region. Bottomfish resources within this area were investigated during conducting an economic study of the fishery. The potential of the NWHI bottomfish resource prompted many new fishers to enter the fishery.

During the late 1970's, the fleet exploited banks closest to the MHI ports. As yields decreased, the fleet moved farther into the NWHI. A few vessels with extended fuel and hold capacity

were fishing around Midway and Kure by 1988. The fishery expanded rapidly in the 1980's and landings peaked in 1987 (Fig. 2). Increased fishing pressure and fluctuating exploitation rates in the NWHI prompted the Western Pacific Regional Fishery Management Council (WPRFMC) to impose a limited access system for a large part of this area in 1989. Currently, effort in the portion of the NWHI west of Necker Island (Fig. 1 ) is limited to 6 vessels.

### Fishing Gear

The Hawaiian snapper fishery utilizes various modifications of traditional Hawaiian handline gear. The gear consists of a main line with a 2–4 kg weight attached at the terminus. Several 40–60 cm sidelines with circle hooks are attached above the weight at 1 m intervals. The basic design of the handline gear used in the fishery has remained essentially unchanged from gear used by early, indigenous Hawaiians.

Commercial snapper fishermen in Hawaii mainly utilize vessels 10–20 m in length. The vessels are usually equipped with color video depth and fish echo sounders, satellite navigation receivers, Single Side Band (SSB) and VHF radios, EPIRB's, and hydraulic line-pulling equipment.

Vessels venturing into the NWHI tend to be in the upper end of the size range, as distance from ports and lack of rough-weather shelter keep many of the smaller vessels closer to their home ports. The MHI vessels, although smaller than those used in the NWHI, are similarly equipped.

There are also many part-time recreational/commercial fishermen in the MHI. The boats involved in this fishery are smaller than the full-time commercial vessels and usually range from 5 to 15 m in length. Most of the part-time fishermen have color video depth/fish sounders, CB radios, and electric line-pulling equipment. Many also have satellite navigation equipment.

Since the late 1960's, the availability of improved navigational and fishing gear has greatly increased the fishing power of both commercial and recreational fishermen in Hawaii. It is now possible to return to a particular fishing spot with great accuracy in various weather conditions using electronic navigation equipment and to target single species using color video sounding equipment. In the past, triangulation from visible onshore landmarks was the most common method of relocating productive fishing grounds. This method can be very accurate, but depends on weather and other conditions beyond the control of the fisherman.

Until recently, many fishermen targeted individual species of snappers, but this strategy is not commonly practiced today. Most fishermen now diversify fishing effort because of decreased catch rates for some of the species. Targeting different species of snapper seasonally, or fishing for pelagic species when bottomfish are scarce, is now commonly practiced.

### Seasons and Markets

The various snapper species are mainly caught during the months of November–February, with peak catches in December. Uku is an exception in that it is heavily exploited during the summer months when it aggregates in shallow water to spawn. Some uku are landed incidentally in December owing to increased fishing pressure on opakapaka which occurs at the same depths as uku.

A large portion of the MHI snapper landings is taken by recreational fishermen; therefore, the NWHI commercial fishery plays an important role in providing a consistent supply of fresh bottomfish to local markets. Generally the demand for fresh fish outstrips the supply. Snapper from various Pacific island nations are imported at times to supplement the supply of local fish. In the past these imports generally were of lower relative quality; however, in recent years the quality of these imports has improved dramatically. The price of these imported fish has also increased but is still lower than that of comparable local fish. The seasonal abundance of these imports can affect the price of the local bottomfish. However, most imports occur during the local low season for bottomfishing, which contributes to a year-round consistent supply of fish.

Most commercial fish in Hawaii are sold at wholesale fish auction houses. The demand for freshness and quality is high. Ex-vessel price can vary considerably depending on the quality of individual lots of fish. Snappers are generally separated into two categories at the auction: 1) large fish for the restaurant fillet market and 2) smaller whole fish for local consumers. Demand from local tourist-oriented restaurants is the major factor in bottomfish market economics. The local consumer market for smaller fish fluctuates to some extent, with peak demand occurring during traditional winter holidays.

## Fishery Data Collection

In Hawaii, fishermen who sell all or part of their catch must be commercially licensed and submit a monthly catch report. These data have been available from the State of Hawaii Division of Aquatic resources (HDAR) since 1948. In the MHI, incomplete reporting, and the "under-the-table" selling of fish by recreational fishermen confound the accuracy of the catch reporting system. In 1984 the WPRFMC initiated a monitoring program at the Honolulu fish auction to provide additional information on bottomfish landings in Hawaii. In 1986 the NMFS assumed responsibility for the program. In 1990, the HDAR began to share monitoring duties with the NMFS on a half-time basis. During the years 1984 through 1987, monitoring was conducted six days per week. This was reduced to five days per week in 1988, and three days per week in 1992. Information collected includes name of vessel or fisherman, date of sale, general area fished, species of fish, number of fish and corresponding weight, price per pound, and buyer. Information is recorded on a data sheet, coded and keypunched for analysis. Until recently, the majority of snapper sold in Hawaii passed through the monitored site. However, beginning in 1991, the majority of NWHI landings were not sold at the monitored site, which increased the difficulty in monitoring total archipelago landings.

An additional problem in obtaining total archipelago catch information is the large number of fish landed by recreational fishermen and not reported. The MHI recreational catch of snapper is impossible to accurately estimate. The large number of small trailerable boats currently registered in Hawaii gives an indication of the magnitude of the problem. Many of these "recreational" fishermen often sell their catch disregarding commercial fishing license requirements. The ease of selling privately to wholesalers, retail fishmarkets, restaurants, supermarkets, peddling, etc., without the proper licenses or reporting, leads to serious underestimation of total state catches.

## Stock Status and Population Dynamics

Several different stock assessment approaches have been applied to the Hawaiian deepwater snapper fishery. These will be reviewed in approximate order of methodological complexity, which is similar to their chronological order in time because of developments in stock assessment methods and/or availability of additional data.

Simple catch per unit of fishing effort (CPUE) of commercial fishermen or research vessel surveys is commonly used as an index of stock abundance. CPUE alone can only provide estimates of relative changes in abundance; but, when coupled with certain assumptions and cast in the proper mathematical framework, it is possible to obtain measures of absolute abundance by estimating a catchability parameter. Catchability can be estimated in several different ways, and one of the more common approaches is to use the catch data in a surplus production model which will also estimate other fishery statistics such as maximum sustainable yield. Ralston and Polovina (1982) used a Schaefer surplus production model in one of the earliest attempts to assess MHI deepwater snapper stocks. The parameters for this model were estimated from a linear regression of yearly CPUE on yearly effort over the time period 1959–1978 (HDAR data). Rather than fit individual models to each species, Ralston and Polovina found that an intermediate level of species aggregation (from the species pool of 8 deepwater snappers) resulted in significantly improved fits to the model. This was apparently due to both depth segregation by species and the multispecies nature of the fishery where, since fishing effort (in fisherman-days) is not necessarily directed at a single species, single species CPUE, calculated by using the aggregate fishing effort, does not reflect that species abundance. Ralston and Polovina sought to aggregate species in the analysis to essentially mimic the aggregate nature of the fishing effort. This optimal level of species aggregation was objectively determined through cluster analysis of species weight composition in HDAR daily commercial catch reports. The potentially complex effects of interaggregation interaction (i.e. predation, competition, and mutualism) were statistically examined and dismissed. Of the four MHI regions examined, statistically significant models were consistently achieved only for the Maui-Lanai-Kahoolawe-Molokai (MLKM) region (Fig. 1), an area which accounts for over 50% of the statewide bottomfish landings. This provided an estimate of MSY per habitat area which was then used in conjunction with other habitat area estimates to extrapolate other regional and total MSY's in the MHI and NWHI. Ralston and Polovina concluded that the MHI aggregate bottomfishery was operating at or near MSY in 1978, and in more recent years both MHI and NWHI landings have consistently exceeded estimates of MSY[4,7] (Polovina, 1987), a situation difficult to interpret for purposes of stock assessment. The next level of stock assessment approaches for Hawaiian deepwater snappers attempted to utilize information on age and growth and patterns of size/age at entry to the fishery on a species-specific level.

Assessment of Hawaiian deepwater snappers in the 1980's relied heavily on the Beverton and Holt (1957) approach, also referred to as dynamic pool modelling. The normal methodology is simply to use the equations presented by Beverton and Holt (1957), inserting where necessary the von Bertalanffy growth coefficient ($K$) or asymptotic length ($L\infty$) parameters, values of total, natural, or fishing instantaneous mortality ($Z$, $M$, or $F$), and ages at maturity or entry to the fishery ($t_m$ or $t_e$). Since this complete set of information is not available for many species of Hawaiian deepwater snappers, alternative methods must often be used to solve the yield equation.

The first alternative method is to estimate independently as many parameters as are within the limits of the

---

[7] S. Ralston and K. E. Kawamoto. 1988. A biological assessment of Hawaiian bottom fish stocks, 1984–87. U. S. Dep. Commer., NOAA, Natl. Mar. Fish. Serv., Southwest Fish. Cent. Admin. Rep. H-88-8, Honolulu, Hawaii, 60 p.

database, and then use empirical relationships to estimate the remaining parameters. Ralston and Kawamoto[7] used this approach for five species of Hawaiian bottomfish (including four species of deepwater snappers: ehu, onaga, opakapaka, and uku), starting with estimates of $L\infty$ and the ratio $Z/K$ from application of the Wetherall et al. (1987) method on catch length frequencies. These length frequencies were converted from Honolulu auction weight data by using the length-weight conversion parameters from Loubens (1980), Uchiyama et al. (1984), Brouard and Grandperrin (1984), and Ralston (1988). The empirical relationship presented in Manooch (1987) was used to estimate $K$ from $L\infty$, and the empirical relationship presented in Ralston (1987) was used to estimate $M$ from $K$. The mortality parameters $Z$ and $F$ were deduced algebraically, where $Z=(Z/K)K$ and $F=Z-M$. Ages at entry were estimated from the ascending limbs of the weight frequency distributions, by using the length-weight conversion parameters and $L\infty$ and $K$ (assuming $T_0=0$). The estimates of $L\infty$ and $K$ were further used to construct a length converted catch curve from the length frequency distributions (also assuming $T_0=0$), resulting in another estimate of $Z$. Ralston (1984) also estimated M from $L\infty$, $K$, and water temperature using the empirical formula given in Pauly (1980). Generally, multiple estimates of a parameter were averaged when they were in close agreement. Ralston and Kawamoto[7] concluded that NWHI stocks were healthy, but most MHI stocks were being growth overfished by excessive harvesting of juvenile fish. They recommended some form of management regulation to counteract this.

The second alternative method is to modify the yield equation to a form which uses the ratios $Z/K$, $M/K$, or $F/K$ rather than $Z$, $M$, $F$, or $K$ since the former are readily calculable by using the Wetherall et al. method on weight-converted length frequency samples from a fished population (where $Z/K=M/K+F/K$) and an unfished population (where $Z/K=M/K$). $F/K$ can then be solved for by subtraction, $F/K=Z/K-F/K$. This was suggested by Polovina (1987) and implemented by Somerton and Kobayashi[8] to calculate the spawning potential ratio (*SPR*=ratio of current spawning stock biomass per recruit to the virgin spawning stock biomass per recruit) for two species of MHI deepwater snappers (ehu and opakapaka). This analysis assumed that length frequencies of NWHI catch approximated a virgin unfished condition. Somerton and Kobayashi[8] concluded that *SPR* values were in the 20–30% range which borders on the 20% value generally accepted as an indicator of recruitment overfishing (Beddington and Cooke[9]).

Both of these ad hoc applications of Beverton-Holt probably suffer from biases because of the variety of approximations and assumptions. One bias potentially affecting both approaches is due to use of the Wetherall et al. method to estimate initial parameters of the analyses. Somerton and Kobayashi (1991) used computer simulation to show that estimates of $Z/K$ and $L\infty$ from the Wetherall et al. method can be either positively or negatively biased for many years while the population is adjusting to a change in fishing intensity or from a recruitment perturbation (however, bias due to recruitment seasonality per se can be negligible [Ralston, 1990]). Even under equilibrium conditions there can be substantial bias due to error in estimating the size at complete fishery selection and growth variability (Somerton and Kobayashi, 1991; Issac, 1990). In their assessment of the 1988 bottomfish stock, Somerton et al.[10] abandoned the Beverton-Holt approach because of uncertainties regarding this type of bias; however, as mentioned previously, Somerton and Kobayashi[8] applied the $Z/K$, $M/K$, $F/K$ version of Beverton-Holt to estimate *SPR* for ehu, which does appear to be in equilibrium, and for opakapaka, for which there are additional data on size at complete fishery selection.

Ralston and his coworkers[2,4,7] (Ralston, 1981, 1984; Ralston and Miyamoto, 1983) have assembled an extensive database on the biology and fishery for opakapaka, which is by far the single best known species of Hawaiian deepwater snapper. For this reason, assessment approaches for opakapaka require fewer assumptions and approximations, and often there are multiple estimates available for a desired parameter. Ralston (1984) and Ralston and Kawamoto[2] applied yield-per-recruit analyses to opakapaka which made use of many independently estimated parameters. Von Bertalanffy parameters were obtained from a study of otolith microstructure (Ralston and Miyamoto, 1983), and $Z$ and $M$ were estimated from length converted catch curves from fished and unfished areas, and age at entry was estimated from the ascending limbs of catch weight frequency distributions, by using length-weight conversion and von Bertalanffy parameters.

Somerton and Kobayashi[8] developed a computationally simple dynamic estimator of *SPR* that makes use of a time series of CPUE and catch size frequencies. Assuming that CPUE is an index of population size, changes in CPUE over time, coupled with the changes in the catch size composition, can be used to make estimates of *SPR*. Resorting to a similar strategy as that of Ralston and Polovina (1982), Somerton and Kobayashi[8] aggregated species in the CPUE index and were able to calculate species-specific dynamic *SPR* for five MHI bottomfish species (including four species of deepwater snappers: ehu, onaga, opakapaka, and uku) by utilizing species-specific catch size frequency distributions and sizes at maturity. These dynamic *SPR* values were similar to the equilibrium SPR values, falling in the range of 20–40%. The earliest

(1948) CPUE data were considered virgin, but it is known that considerable bottomfishing may have been taking place at least as early as the 1930's (Polovina, 1987); and no attempt was made to correct for technological improvement in fishing efficiency. Clearly, there is a need for some type of dynamic stock estimator which does not rely on CPUE.

The logical alternatives are dynamic production modelling or age-structured models. The former approach is handicapped by incomplete landings and effort data, and the lack of a reliable CPUE. The latter approach may be more suitable, particularly since more age and growth data are available from ongoing otolith studies. Preliminary application of stock-synthesis, an age-structured model developed by Methot (1989, 1990), to NWHI opakapaka has been favorable[11], and a synthesis-like equilibrium approach called IMMAGE (Somerton and Kobayashi, 1992) has been successfully used to estimate recruitment, fishing mortality, and the gear selection curve for MHI and NWHI opakapaka[11]. Currently, the 1991 stocks are assessed with the CPUE-based dynamic *SPR* method.

### Management and Regulation

Current fishing regulations for Hawaiian deepwater snappers include commercial minimum size limits of 1 pound for opakapaka, onaga and uku, and limited entry in the NWHI. There are no bag limits, closed seasons, or recreational minimum size limits for any deepwater snapper.

Somerton and Kobayashi[12, 13] explored the possible consequences of increasing the minimum size limit for opakapaka from 1 to 3 pounds or initiating a 1–3 month seasonal closure of the fishery. Their results from computer simulation indicated that both management strategies could substantially benefit the fish population in terms of increasing the spawning stock biomass. The potential increases ranged from 15–300% after a time period of 5–10 years, depending on the initial condition of the stock. Maximal benefits are attained if sublegal fishing mortality is minimal (i.e. small fish are avoided or released alive) in the case of a size limit increase, and if a seasonal closure effectively reduces the total annual fishing mortality (i.e. there is no compensatory increase in fishing effort during the open season). It is unlikely that the long-term equilibrium yield would increase; however, the population would be less vulnerable to recruitment overfishing and the associated catastrophic stock decline. The State of Hawaii is currently evaluating these and other management options (e.g. bag limits, areal closures) in response to concerns of deepwater snapper overfishing, primarily in the MHI.

### Research Needs Pertaining to Management

Details of the reproductive biology are minimally adequate for most of the primary Hawaiian deepwater snapper species. More age and growth studies are needed, particularly for the younger and smaller fish, with enough data to better define the magnitude of growth variability. Discrepancies in growth estimation due to methodological differences in aging (e.g. Morales-Nin and Ralston, 1990; Radtke, 1987; Smith and Kostlan, 1991) need to be addressed and resolved, as this information forms the foundation for cohort/virtual population analysis, or stock synthesis assessment models. Movement patterns of adults and the extent of egg and larval dispersal need further study to clarify the identity of individual stocks, which would help determine the temporal and spatial scale for effective management.

### Acknowledgments

We would like to thank Jeff Polovina and Bob Moffitt at the NMFS Honolulu Laboratory, Steve Ralston at the NMFS Tiburon Laboratory, and one anonymous reviewer for their helpful comments on the manuscript.

*Abstract.*—Deepwater snappers are a valuable component of fisheries on slopes and banks in Hawaii and in much of the world's tropics. Their ecology and trophic relationships in these deepwater habitats are poorly known. Line fishing in this study simultaneously collected six of the seven lutjanid species that commonly occur in the major deepwater snapper fishery at Penguin Bank, Hawaii. The catch rate of each species showed diel variability; the patterns of some species were distinctly different. The depth distribution of feeding, as indicated by depth of capture, differed considerably among species; all species were taken within several meters of the bottom. Size (fork length) of the predator species did not appear to be stratified by time of capture (daylight versus darkness) or median capture depth. Regurgitation of gut contents seemed to be reduced when fish were retrieved at a rate that was slower than used in commercial practice but rapid enough to prevent death or morbidity while hooked. The food remaining in line-caught specimens appeared to be representative of what was originally eaten. The six snapper species ate considerable amounts of a wide range of pelagic animals and demersal fishes and much smaller quantities of a few invertebrate benthic groups. *Etelis coruscans*, *Etelis carbunculus*, and *Aprion virescens* formed a distinct, primarily piscivorous feeding guild. *Pristipomoides filamentosus* and *Pristipomoides sieboldii* formed a distinct guild dominated by zooplankton feeding. The few specimens of *Pristipomoides zonatus* appeared somewhat intermediate in diet. Important planktonic prey groups included crustaceans, pteropods, and large, pelagic, colonial urochordates (e.g., salps). Urochordates made a significant contribution to the diet even for some of the primarily piscivorous species. Major diel and seasonal shifts in diet were found only in *P. filamentosus*; they involved the relative proportions of fish, and especially of the major planktonic groups. Our information on diet composition and depth and time of feeding (catch) suggests that considerable resource partitioning occurs among these deepwater snappers.

Deepwater lutjanid snappers represent an important resource throughout the tropical and subtropical oceans of the world. Many species of Lutjanidae are highly prized as food fish and typically have a high market value wherever they are found (Polovina and Ralston 1987). In the tropical Pacific, several genera of these fishes inhabit the slopes of land masses and banks at depths of 100–400 m. Understanding the trophic support for these fishes in this environment can provide important insight for management of their fisheries. Published studies of the diets of deepwater snappers are scarce, however, because these fisheries occur in isolated locations, and collecting gut contents from such deepwater fishes is difficult (Parrish 1987).

In Hawaii, deepwater lutjanid snappers are the mainstay of the commercial and recreational bottom fish fishery, contributing over 88% by weight and 93% by value of the total commercial deepwater bottom fish landings in 1990 (HDAR 1991). Bottom fishing is mainly concentrated on the steep slopes of deepwater banks. These banks and the deep slopes of island coasts have an aggregate area over six times that of shallow-water reefs in the state (Agegian et al. 1988). Similar grounds support existing or potential snapper fisheries in much of the Pacific and other tropical waters (Polovina and Shomura 1990). Our limited understanding of the ecology and production of deepwater banks suggests that these important habitats probably function very differently from shallow-water coral reef ecosystems. The interaction between currents, the daily tidal regime, and the physical structure

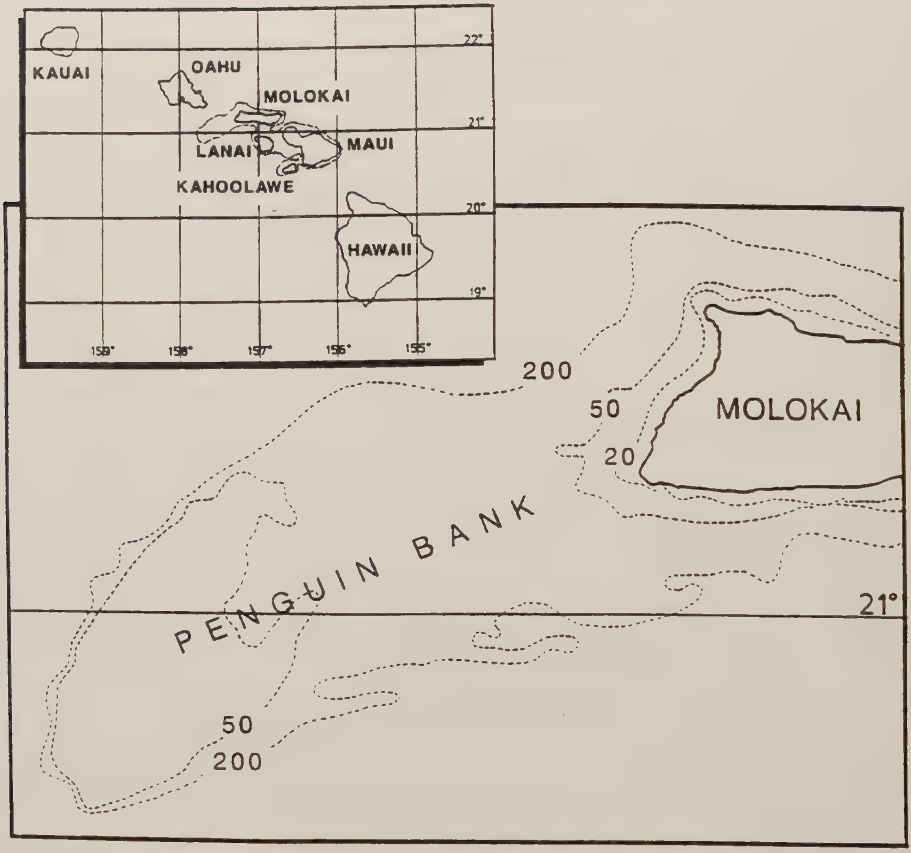

FIGURE 1.—Penguin Bank and immediate surroundings in the Hawaiian Archipelago. Bathymetric contours are in meters. The Molokai–Lanai–Kahoolawe–Maui bank complex is indicated generally by the bathymetric contour (200 m) in the inset.

of the banks may produce hydrographic features that are distinctive and have different effects on system productivity (Agegian et al. 1988).

The Molokai–Lanai–Kahoolawe–Maui bank complex (Figure 1), of which Penguin Bank is a large part, produces about 41% of the commercial bottom fish catch of the main Hawaiian Islands (based on 1990 landings statistics from the Hawaii Division of Aquatic Resources). In addition, there is a large but unrecorded recreational catch (Ralston and Polovina 1982; WPRFMC 1986). After recent heavy fishing pressure, there are indications that some stocks on these banks have been overfished and are declining (Ralston and Polovina 1982; Ralston 1984; Ralston and Kawamoto 1985, 1988; HDLNR 1986; WPRFMC 1986, 1988). Knowledge of these stocks is based almost entirely on data from landings by the commercial handline fishery. Some information is available on basic life history characteristics (e.g., growth parameters, reproductive data, size data, and mortality rates) of some major species in the fishery (Ralston 1981; Everson 1984; Kikkawa 1984; Kikkawa and Everson 1984; Uchiyama et al. 1984; Uchiyama and Tagami 1984; Sudekum et al. 1991). However, little is known about the habitat, food resources for bottom fish, or other characteristics of the environment that make it a productive fishing ground.

Except for some data on the diet of the greater amberjack *Seriola dumerili* (Humphreys and Kramer 1984), almost nothing is known about the feeding ecology of the commercial bottom fishes at Penguin Bank. Trophic information for these species from other localities also is sparse. One jack species (*Pseudocaranx dentex*) has been studied by Seki (1984a), two snapper species (*Pristipomoides auricilla* and *Pristipomoides zonatus*) by Seki and Callahan (1988), and two other jacks (giant trevally *Caranx ignobilis* and bluefin trevally *Caranx melampygus*) by Sudekum et al. (1991). All available diet information on deepwater groupers and snappers has been surveyed by Parrish (1987), including results from elsewhere in the Hawaiian Archipelago obtained by Kluegel (1921) and Seki (1984b) and previously unpublished results on diets of fishes from the Northwestern Hawaiian Islands (NWHI) and the Marianas.

The overall goal of our study was to identify and characterize key relationships between commercially important deepwater bottom fishes and their habitats and major food sources. Specific objectives were (1) to determine whether there is overlap among deepwater lutjanid snappers in their depth ranges or feeding periods, (2) to identify important prey groups in the diets of these species and estimate their relative importances, (3) to determine the extent of overlap in diet for these predators, and (4) to identify any diel or seasonal shifts in their diets.

## Study Area

Penguin Bank is a large underwater feature immediately southwest of the island of Molokai, Hawaii (Figure 1). The top is relatively flat, with depths of 50–100 m; at the periphery, the bathymetry drops rapidly to over 500 m (Gregory and Kroenke 1982). Penguin Bank is similar in depth to the other banks in the Hawaiian Archipelago, and production dynamics on Penguin Bank are probably representative of many such banks in Hawaii and elsewhere in the tropics. Suitable habitat for bottom fish seems to be limited to a small and rather scattered fraction of the entire Penguin Bank area (C. R. Agegian, University of Hawaii, J. J. Polovina, Honolulu Laboratory, National Marine Fisheries Service, and S. Ralston, Tiburon Laboratory, National Marine Fisheries Service, personal communications).

## Methods

*Specimen collection.*—Several areas of Penguin Bank known as commercially productive fishing grounds were chosen for specimen collection. These sites were surveyed hydroacoustically with a Raytheon model LSR-910M and a Simrad type EQ38-MK3 paper-recording fathometer, a RD Instruments series RDVM acoustic doppler current profiler, and a Furuno model CN106 color chromoscope.[1] Information was collected on bathymetry, substrate type, and fish aggregations. Some nearby areas on top of the bank also were fished to obtain adequate diet samples from the snapper *Aprion virescens*.

Specimens were collected between October 1987 and December 1989, primarily by conventional bottom handlines deployed from hydraulic fishing gurdies (Uchida and Uchiyama 1986:29). Five stations were fished with a Kali bottom longline developed at the National Marine Fisheries Service's Honolulu Laboratory (Shiota 1987). The use of rigid polyvinylchloride tubing in this gear in place of conventional gangions or dropper lines greatly reduced problems with fouling on the rough bottom. Stripped squid was used for bait for all handlining and longlining. All hooks were fished within a few meters of the bottom.

A handline fishing station consisted of a series of drifts made over a selected site after wind and current directions were determined. Drifts varied in response to local conditions and topography, but a typical station was occupied 1–3 h, during which time sampling occurred at depths ranging from about 100 to 250 m. An effort was made to sample the complete depth range fairly evenly throughout the diel cycle. Total fishing effort was 248 line-hours during daylight (0600–1830 hours) and 294 line-hours during darkness (1830–0600 hours). The shallow (0–150 m) and deep (150–300 m) depth ranges were each fished at least 90 line-hours during each period (daylight and darkness). In the standardized fishing, each 50-m depth interval from 50 to 300 m was handlined for a minimum of 25 line-hours. At least 20 line-hours of effort were exerted in each 2-h time interval throughout the diel cycle (Table 1). Effort was not equal for various times of day and depths, so most catch data were expressed as handline catch per unit effort (CPUE).

To determine if there were species-specific patterns of temporal and spatial distribution, the handline catch of each species, expressed as a fraction of the total handline catch of all species, was compared by chi square analysis ($\chi^2$) to a uniform distribution of expected (equal) catch of all species. This procedure was used separately for each 2-h interval of the day and for each 50-m interval of depth fished.

---

[1] Mention of products or names of manufacturers does not imply endorsement by the U.S. Government.

Because regurgitation of gut contents is a problem when line-caught fish are brought to the surface rapidly by commercial fishing methods, various decompression schedules were tested. Lines were retrieved at different rates, and the general condition of each fish and the extent to which it had regurgitated were recorded. The most visible sign of barotrauma was the eversion of the stomach forward through the esophagus, caused by the expansion of gas in the swim bladder. To quantify the potential for loss of gut contents by regurgitation, each fish was assigned an integral value (ranging from 0 to 4) reflecting the degree of extrusion of the stomach into the mouth cavity. Time, depth, and location of capture, rate of ascent, and regurgitation state value were recorded for each specimen. The mouth and gills were examined for regurgitated material (which was included in diet analysis), and the specimen was weighed (to the nearest 0.01 kg), measured (standard length, fork length, and total length to the nearest 1 mm) and sexed (by macroscopic appearance of gonads after dissection). Fish were cooled quickly, and within 1 h after capture, the gastrointestinal tract was removed and frozen. Altogether, 589 fish were collected. All identifiable prey items from 219 of these predator specimens were used in trophic analysis.

*Trophic analysis.*—Diet composition was determined by examining the contents of the entire gastrointestinal tract of each specimen, following procedures similar to those described in Hyslop (1980), Harrison et al. (1983), and Parrish et al. (1985). All prey organisms were identified visually under magnification to the lowest feasible taxon. All prey individuals were counted, and the volume of individuals or groups of individuals was measured by liquid displacement. If a prey individual was in an advanced state of digestion, its volume was estimated by comparing it with intact individuals of similar size and known volume. Parts of partially digested prey were measured (e.g., with an ocular micrometer) to permit estimates of the sizes of the intact individuals.

TABLE 1.—Distribution of total standardized handline fishing effort applied simultaneously for six snapper species collected at Penguin Bank, Hawaii, in 1987–1989.

| Effort distribution by time of day | | Effort distribution by depth | |
|---|---|---|---|
| Time of day (hours) | Effort (line-hours) | Bottom depth (m) | Effort (line-hours) |
| 0000–0200 | 27.8 | 50–100 | 25.4 |
| 0200–0400 | 20.2 | 100–150 | 188.8 |
| 0400–0600 | 29.1 | 150–200 | 188.9 |
| 0600–0800 | 41.9 | 200–250 | 110.1 |
| 0800–1000 | 37.8 | >250 | 28.0 |
| 1000–1200 | 54.3 | | |
| 1200–1400 | 37.4 | | |
| 1400–1600 | 32.6 | | |
| 1600–1800 | 43.0 | | |
| 1800–2000 | 62.0 | | |
| 2000–2200 | 128.8 | | |
| 2200–2400 | 27.4 | | |

Diet composition was expressed in terms of number and volume of prey items and frequency of occurrence of predator guts containing the prey. An index of relative importance (IRI) for each prey category in the diet was calculated with the method of Pinkas et al. (1971):

$$\mathrm{IRI} = F(N + V);$$

$F$ = percentage of all predator individuals that contained that prey category,

$N$ = percentage of total prey individuals that were of that category, and

$V$ = percentage of total prey volume that was of that category.

To compare diets, the IRI of a particular prey category was expressed as a fraction of the sum of IRI values for all categories at comparable levels of systematic or ecological organization.

Diet overlap between predator groups was calculated by the Morisita–Horn $C_\lambda$ formula (Horn 1966):

$$C_\lambda = \frac{2\sum_{i=1}^{s}(x_i y_i)}{\sum_{i=1}^{s} x_i^2 + \sum_{i=1}^{s} y_i^2};$$

$s$ is the total number of prey categories, and $x_i$ and $y_i$ are the proportions of the total diet index of predator group $x$ and $y$ that are taken from prey category $i$. Values of $C_\lambda$ can vary from 0 when diets of two groups are completely distinct to 1 when the diets are identical. Diet overlaps were classified with Langton's (1982) scale: low overlap, 0–0.29; medium overlap, 0.30–0.59; and high overlap, ≥0.60. Groups compared for diet overlap included different predator species, predators collected in different seasons and at different times of day, and different portions of the alimentary tract (i.e., stomach, mouth and hindgut).

TABLE 2.—Six deepwater snapper species collected in this study, by number and size caught, time of day, and depth of capture, at Penguin Bank, Hawaii, in 1987–1989.

| Species | Number collected | Fork length (mm) |  | Time of day caught (hours) | Depth of capture (m) |  |
|---|---|---|---|---|---|---|
|  |  | Range | Median |  | Range | Median |
| *Pristipomoides sieboldii* | 147 | 237–435 | 363 | 0036–2242 | 104–265 | 168 |
| *Pristipomoides filamentosus* | 232 | 267–654 | 388 | 0010–2348 | 49–256 | 107 |
| *Pristipomoides zonatus* | 7 | 322–410 | 387 | 0915–1806 | 150–190 | 164 |
| *Etelis coruscans* | 40 | 265–836 | 404 | 0540–1905 | 163–331 | 192 |
| *Etelis carbunculus* | 92 | 232–576 | 346 | 0150–2258 | 73–280 | 175 |
| *Aprion virescens* | 71 | 443–890 | 633 | 0615–1850 | 46–134 | 51 |
| Total | 589 |  |  |  |  |  |

Statistical analyses were done on a microcomputer with the software package SAS PC Release 6.03 (SAS Institute 1985, 1988).

## Results

### *Catch Composition*

Six of the eight native lutjanid snapper species known from Penguin Bank were captured in this study (Table 2). The only common, native, deepwater lutjanid of this habitat not present in the catch was *Aphareus rutilans*.

*Pristipomoides sieboldii* and *Pristipomoides filamentosus* made up 64% of the catch; *P. zonatus* was caught only incidentally (1%). *Etelis coruscans* and *Etelis carbunculus* made up 23% of the catch. *Aprion virescens*, an important commercial species in summer, accounted for 12% of the total.

### *Spatial and Temporal Distribution of the Catch*

The distribution of depths and times of catch of most of the six snapper species overlapped somewhat, but some distinct species differences were discernible. *Pristipomoides filamentosus* seemed to take bait most readily during the morning (0400–0800 hours) and evening (1600–2200 hours) (Figure 2A). *Pristipomoides sieboldii* seemed to feed in a less regular temporal pattern with several peaks during the day and night. The highest catch rates of the *Etelis* species were widely separated in time; *E. coruscans* took bait most readily during 0600–0800 hours and *E. carbunculus* during 1800–2000 hours (Figure 2B). *Aprion virescens* was caught throughout the daylight hours, and seemingly was inactive during most of the night. The pooled CPUE for all snappers (which are targeted as a group in the snapper fishery) fluctuated over a diel cycle, with peaks during 0400–0800 hours and 1800–2200 hours. The pooled catch rate declined from 2200–0400 hours.

Distributions of CPUE at discrete depth intervals indicated that *A. virescens* took bait most readily in the shallowest zone occupied by these species (Figure 3B). Its distribution overlapped with that of *P. filamentosus*; however, the CPUE of the latter was highest in a deeper zone (100–150 m) (Figure 3A). The CPUE of *E. coruscans* was very low in all except our deepest (250–300 m) standardized fishing zone. The catch depth distributions of the two *Etelis* species overlapped, but the CPU for *E. carbunculus* was highest at 200–250 m depth and substantial at shallower depths. The catch depth distributions of the *Pristipomoides* species overlapped with that of *E. carbunculus*, but the peak CPUE of each species was in a different depth range. The peak CPUE for *P. sieboldii* was at 150–200 m. *Pristipomoides zonatus* was caught in the same depth range as *P. sieboldii*, but too few *P. zonatus* were caught to determine the depth where CPUE peaked. The depth range of some of these species may extend deeper than 300 m. However, local underwater observations (S. Ralston, personal communication) and research elsewhere in the tropical Pacific (Ralston and Williams 1988) suggest that none of the species has major peaks in abundance at depths exceeding 300 m.

Chi-square goodness-of-fit analysis indicated that within each depth and time interval sampled, catches (relative abundances) of these species varied significantly from an "expected" uniform distribution of equal catch of all species ($\chi^2$ = 11.73–521.04, df = 5, $P$ = 0.01–0.005). The nonuniform

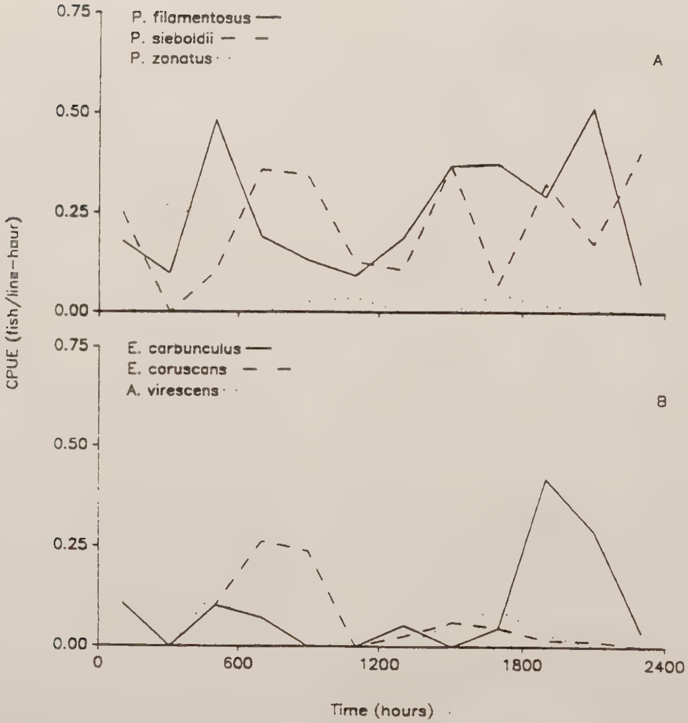

FIGURE 2.—Diel pattern of catch per unit effort (CPUE) of (A) three *Pristipomoides* species, and (B) two *Etelis* species and *Aprion virescens*, at Penguin Bank, Hawaii, 1987–1989.

dispersion of catches suggests that the differences in observed interspecific temporal and depth patterns of catch are related to real interspecific differences in patterns of predator occurrence and feeding.

To determine whether fish size was related to depth or time of capture, the catch data were tested by both median comparison tests and nonparametric correlation analysis. No significant correlation was found between fork length and capture depth for any of these species (Spearman's rank correlation analysis: $r_s = -0.13$–$0.29$, $P = 0.17$–$0.92$). For each of the species, median fork lengths of fish caught during daylight (0600–1830 hours) and darkness (1830–0600 hours) were not significantly different (Wilcoxon's signed-rank test: $Z = 0.98$–$1.61$, $P = 0.10$–$0.32$).

### *Fish Retrieval Rate and Regurgitation*

The effect of fish retrieval rate on regurgitation was tested for all species by Spearman's rank correlation analysis. No clearly significant correlation was found between rate of ascent and regurgitation index ($r_s = -0.23$–$0.01$, $P = 0.06$–$0.93$). However, qualitative observations indicated that a retrieval rate of about 0.5 m/s was optimal in terms of fish condition and fishing success. Fish retrieved rapidly (≥2 m/s) or very slowly (≤0.1 m/s) exhibited signs of traumatic decompression, including extreme eversion of the stomach through the esophagus, and bulging eyes. However, fish retrieved at intermediate rates of ascent (about 0.3–0.6 m/s) usually showed less traumatic signs of decompression and were often lively at the surface. Size of fish did not seem to affect the extent of regurgitation; the Spearman coefficients comparing fork length with regurgitation index were nonsignificant for all species ($r_s = 0.01$–$0.14$, $P = 0.72$–$0.94$). No significant correlation could be found between regurgitation index and the depth at which a fish was hooked (depth range, 49–280 m; $r_s = -0.007$–$0.27$, $P = 0.22$–$0.45$).

### *Trophic Analysis*

Analysis with diet overlap indices based on percent IRI indicated that for each species, the com-

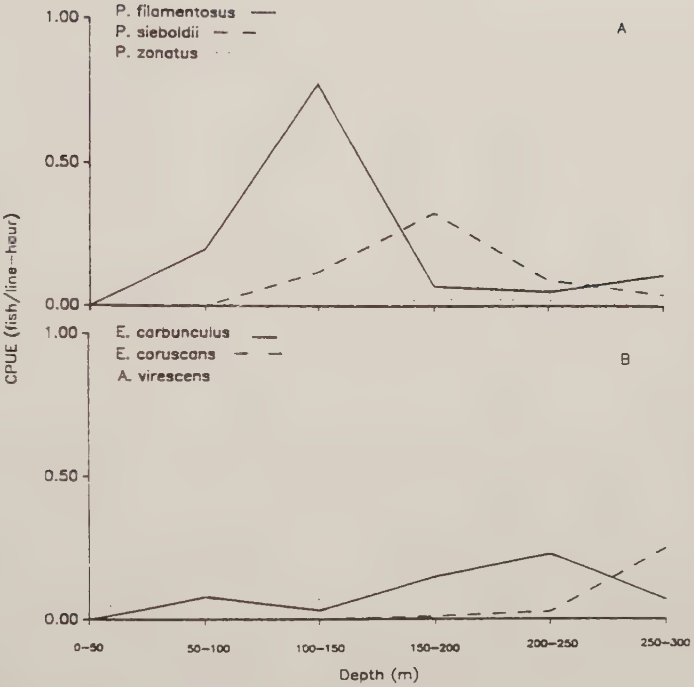

FIGURE 3.—Depth distributions of catch per unit effort (CPUE) of (A) three *Pristipomoides* species, and (B) two *Etelis* species and *Aprion virescens*, at Penguin Bank, Hawaii, 1987–1989.

position of prey items found in the hindgut, stomach, and mouth was similar ($C_\lambda$ > 0.5 for diet overlap between gut locations for each snapper species). Therefore, all prey items from the entire alimentary tract of an individual were pooled for diet calculations.

As a group, the snappers ate large amounts of a wide range of pelagic animals and much smaller quantities of a few benthic groups (Table 3; Appendix Table A.1). Five of the snapper species were separable by diet into two general feeding guilds: (1) zooplanktivores that fed primarily on pelagic urochordates, planktonic crustaceans, and pteropods, and (2) species that were primarily piscivorous (Table 3). Zooplankton composed 92% and 97% of the total IRI in the diets of *P. filamentosus* and *P. sieboldii*, respectively. *Etelis coruscans*, *E. carbunculus*, and *A. virescens* were primarily piscivorous; fish accounted for 81–98% of the total IRI.

*Pristipomoides* species fed on pelagic urochordates (mainly thaliaceans); these prey were most prevalent in the diet of *P. filamentosus* (47% of total IRI). *Pristipomoides sieboldii* also fed on thaliaceans (16% of total IRI), but pelagic crustaceans (47%) and pteropods (29%) were more important prey items. Pelagic crustaceans and pteropods were also important in the diet of *P. filamentosus*. *Pristipomoides zonatus* fed on thaliaceans (38% of total IRI), but also preyed on fish (55%) and benthic crustaceans (6%). In the piscivorous guild, pelagic urochordates, cephalopods, and benthic crustaceans also were notable prey items.

The two feeding guilds were clearly distinguished by their $C_\lambda$ values. Exclusive of *P. zonatus*, $C_\lambda$ values ranged from 0.78 to 1.00 within guilds (Table 4), and little dietary overlap occurred between guilds ($C_\lambda$ = 0.03–0.23). *Pristipomoides zonatus* (only six specimens) fell somewhat between guilds: it showed high overlap with the piscivorous guild ($C_\lambda$ = 0.76–0.87) and medium–low overlap with the zooplanktivorous guild ($C_\lambda$ = 0.18–0.55).

Major diel and seasonal diet changes were found only for *P. filamentosus*. Its $C_\lambda$ value (based on

TABLE 3.—Diets of six deepwater snapper species collected at Penguin Bank, Hawaii, in 1987–1989. Gut contents of 219 fish were divided into 12 major systematic or ecological groups. Relative abundance of prey is expressed as percentage of total index of relative importance (IRI). Numbers in parentheses indicate the number of guts with any identifiable contents.

| Prey group | Percent IRI in gut contents of | | | | | |

[a] Larvae are included in "Pelagic small crustaceans."

IRI) for day versus night samples was 0.50. Pelagic urochordates composed a much greater part of the total IRI of individuals caught at night (Table 5). Other major components of the diet (e.g., fish, pelagic crustaceans) were more prevalent in specimens caught during the day. Seasonally, pelagic urochordates were low in the summer IRI of *P. filamentosus*, increased in winter, and became strongly dominant in spring (Table 5). As urochordates increased, groups such as pelagic crustaceans, pteropods and fish, which had composed sizable percentages of the IRI in summer or winter, decreased to low spring levels. Seasonal $C_\lambda$ values for *P. filamentosus* reflected the fluctuating importance of pelagic urochordates in the diet. Values of $C_\lambda$ for summer versus winter (0.78) and spring versus winter (0.71) were similar. However, the shift of the major diet component from pelagic crustaceans in summer to pelagic urochordates in spring resulted in a $C_\lambda$ value of 0.34 in the summer versus spring diet comparison. The diet of each piscivorous species was highly similar throughout the diel and seasonal cycles; the range of $C_\lambda$ values was 0.62–0.99.

## Discussion

### *Fish Retrieval Rate and Regurgitation*

Regurgitation of gut contents due to rapid decompression remains a problem for trophic studies of deepwater physoclistous fishes. We found that retrieval at a very slow rate to allow resorp-

tion of gases from the swim bladder is not a satisfactory solution. Fish retrieved at the slowest rates often showed the same signs of barotrauma as those retrieved rapidly. Their inactivity when landed and lack of the usual signs of life suggest that death or debilitation is common after a long period on the line. Such fish may have reduced physiological capability to resorb gas from the bladder (perhaps because of loss of nervous control of the oval; Harden Jones 1957). However, fish retrieved at an intermediate rate (about 0.5 m/s) appeared to be less severely affected and often contained intact stomachs or retained a substantial amount of prey in the mouth, gills, and gill rakers. Our results suggest that retrieving at moderate rates produces specimens usable for diet studies and is a practical procedure for a field sampling program.

Subsurface handling of individual fish by divers may be one way of reducing the problem of barotrauma in physoclistous fishes (Parrish and Moffitt 1993). However, this technique is not feasible with intensive fishing operations such as those used in the present study.

Our results suggest that the entire gastrointestinal tract should be examined to obtain the maximum diet information from a given sample. In this study, the diversity and composition of prey found in the intestines were sufficiently similar to those found in the stomach and mouth that prey from all parts of the alimentary tract could be pooled for dietary analysis. However, some of the soft-bodied prey (especially larval fishes) seemed to be underrepresented in the intestinal samples. Movement of food through the digestive tract of these fishes seems to be fairly rapid. "Palu" (a fish attractant composed of minced fish and oats) was found in the hindgut of three species (*A. virescens, P. filamentosus, E. coruscans*) caught 1–2.5 h after it was first released in the water.

### *Trophic Analysis*

Our data indicate that a distinct feeding guild with a strongly zooplanktonic diet occurs among the lutjanid snappers at Penguin Bank. These results, together with the reports for deepwater snappers elsewhere in the tropical Pacific (Parrish 1987), suggest that zooplanktivory may be an important trophic mode among *Pristipomoides* species. Examination of our data from all Penguin Bank cruises showed that zooplankton dominated the diets of *P. filamentosus* and *P. sieboldii* throughout the year, and levels of piscivory remained low. The diet composition of species of the piscivorous guild (*A. virescens, E. coruscans,* and *E. carbunculus*) remained relatively constant throughout the day and seasons of the year. *Pristipomoides zonatus* may have a more generalized diet than species in the planktivorous or piscivorous guilds. Our six specimens of *P. zonatus* contained substantial amounts of both benthic–demersal and pelagic forms. This same trend was reported for a larger sample ($N = 106$) of this species occurring in the Marianas (Seki and Callahan 1988).

As is commonly the case with analysis of fish gut contents, most of the fish prey we found in these deepwater snappers were not identifiable even to major groups. The identifiable fish prey were diverse systematically and ecologically, and included relatively sedentary species, fishes with generally demersal habits at a variety of depths, fishes of the water column near bottom, and mesopelagic species (Appendix). There was rather good correspondence between what is known of the common depth ranges of the various prey fishes and the depths at which the particular snapper species that ate them were collected.

The deep-feeding *Etelis* species contained a deepwater demersal cardinalfish *Epigonus* sp. and three identifiable mesopelagic fishes: the bristlemouth *Argyripnus brocki* and the lanternfishes *Benthosema fibulatum* and *Diaphus* sp. All these mesopelagic species have been identified as components of the distinctive "mesopelagic-boundary community" of Hawaii, which inhabits coastal waters over bottom depths of perhaps 100–700 m in a band surrounding islands and banks (Reid et al. 1991; S. B. Reid, University of Hawaii, personal communication). Of these species, at least *Benthosema fibulatum* and some *Diaphus* species perform some diel vertical migration and could be eaten well above the bottom at some times of the day. A number of the other, primarily demersal, prey species in the snapper diets also range higher in the water column at times and may be subject to midwater predation, especially during their younger life stages. The deepwater snappers may eat such prey only at the bottom, but these prey could provide a short link with productivity originating higher in the water column.

Monacanthidae (many identifiable as *Pervagor* sp.) were the most nearly ubiquitous prey fish, occurring in all the snapper species except one and composing at least a few percent of the diet of some. Species of *Pervagor*, especially the fantail filefish *P. spilosoma*, occasionally become extremely numerous and widely consumed by piscivorous fishes in Hawaii, at least in shallow waters (Tinker 1978; Brock 1984, 1985; Sudekum et al. 1991). At such times, this species seems to modify its usual behavior and occupies much of the water column as well as its usual demersal habitat (T. A. Clarke and S. B. Reid, University of Hawaii, personal communication). The abundance of monacanthids was not monitored at the specific times and locations of our collections. However, visual censuses made from submersibles on the top and upper slopes of Penguin Bank at 61–117 m depth between October 1985 and February 1988 (overlapping our study) showed that *P. spilosoma* was among the few most abundant fish species present on artificial reefs (F. A. Parrish, Honolulu Laboratory, National Marine Fisheries service, personal communication). The abundance of monacanthids in snapper diets may indicate opportunistic feeding during sporadic abundance of a particular prey.

Fishes recognizable as larval stages occurred with fairly high frequency in the guts of *P. sieboldii*, *P. filamentosus*, and *A. virescens*, but numbers and volumes eaten and the corresponding IRI values were rather low (Appendix). It seems likely that many larval fishes were among the unidentified fish remains or other unrecognizable gut material. The identified larval fish material was concentrated in the zooplanktivorous guild, but some was consumed by the shallowest feeding piscivore. This suggests that the larval fishes occurred and were captured along with invertebrate plankton.

For most of these snapper species, diet data from other sources are based on 1–60 specimens, except for 209 specimens of *P. zonatus* (Parrish 1987). These uneven data suggest that fish prey vary from fairly important to strongly dominant in the diets of these species in other localities. Results for *P. filamentosus* from the NWHI (Parrish 1987) indicated somewhat greater piscivory than at Penguin Bank. *Aprion virescens* and *E. carbunculus* in the NWHI were strongly piscivorous (as at Penguin Bank), and *P. zonatus* appeared more intermediate between piscivory and planktivory (Parrish 1987).

The diets of Penguin Bank snappers contained no identified prey fish species in common with snappers in the other Pacific localities reported. (In all the studies, relatively few prey fishes were identified to species.) Prey families shared by deepwater snappers at Penguin Bank and at other Indo-Pacific localities included Congridae, Apogonidae, Myctophidae, Synodontidae, Balistidae, and Ostraciidae, as well as unidentified tetraodontiform fishes (Parrish 1987).

Cephalopods (including octopus and squid) at Penguin Bank were eaten by all but one snapper species studied there, sometimes providing several percent of the diet (Appendix). The two *Etelis* species, which occurred deepest of all the snappers, contained deepwater ommastrephid and chiroteuthid squid. An early juvenile onychoteuthid species with somewhat shallower distribution was eaten by the shallower-feeding *P. sieboldii*. Cephalopods (including Ommastrephidae) have been found in the diets of all except two deepwater snapper species reported from elsewhere in the Pacific (Parrish 1987). They were fairly important in the diet of *P. filamentosus* in the NWHI.

Several groups of small malacostracans and the larvae of a few groups of large ones made up the bulk of the pelagic crustacean prey category in our study (Appendix). For some small crustaceans (e.g., amphipods, ostracods, isopods), it is not clear whether the habitat was pelagic, benthic, or both. However, these groups commonly occurred in fish guts with other clearly pelagic groups. Larval, juvenile, and adult lobsters, shrimp, and especially crabs and stomatopods were found in the diets of the snappers. Among identified stomatopod prey, species of *Squilla* and *Lysiosquilla* are moderately common as adults in shallow waters of Hawaii and may occur deeper as well. Adults of *Odontodactylus* spp. are unknown from shallow waters in Hawaii, but they have been trawled occasionally from deeper, soft bottoms (well below 100 m). Most of the large crustaceans in the diet were clearly benthic inhabitants as adults (e.g., the deepwater galatheid crab *Munida* sp.). Diet studies of deepwater snappers from other localities (Parrish 1987; Seki and Callahan 1988) have revealed amphipods, euphausids, isopods, crab and stomatopod larvae, and adult benthic crabs (including *Munida* sp. and other galatheids), stomatopods, shrimp, and lobsters.

Pelagic pteropods, including a major component from the family Cavolinidae, were eaten by three snapper species at Penguin Bank and were important prey for two species (Table 3, Appendix). Pteropods of the family Cavolinidae were a minor component of the diet of *P. zonatus* in the Marianas, fairly common in *P. multidens* in Western Samoa, and very abundant in *P. auricilla* in the Marianas (Parrish 1987; Seki and Callahan 1988).

The abundant pelagic urochordates, which were found in all the snapper species at Penguin Bank, included Salpida (probably a dominant group, but difficult to identify as remains), Doliolida, and Pyrosomida (Appendix). Pelagic urochordates (dominantly *Pyrosoma* sp.) have been identified in the diets of all except two deepwater snappers studied elsewhere in the Pacific (Parrish 1987). Siphonophores (dominantly Calycophora), a minor prey item for two snapper species at Penguin Bank (Appendix), have also been found in the diet of *P. auricilla* in the Marianas (Parrish 1987).

Pelagic urochordates and siphonophores might seem at first to offer little nutrition and to be unlikely preferred prey. Both are gelatinous, and the filter-feeding urochordates contain an indigestible cellulose tunic. However, both groups can concentrate large amounts of captured plankton prey in their guts (up to 20% of the body weight in some urochordates; Kashkina 1986), thus increasing their overall value as food. Both groups are colonial and form large interconnected aggregations of many individuals. They may enable snappers to forage with high efficiency. The frequency and abundance with which these soft-bodied megaplankton, together with the ciliary-feeding pteropods, appear in diets of most deepwater snappers sampled in the Pacific (Parrish 1987) suggest that they make a substantial contribution to the nutrition of demersal deepwater fish populations.

It is widely believed that these snapper species are strongly demersal (*A. virescens* less so than the others). This belief is based on behavior of related species, interpretation of sonar chromoscope images, much experience of commercial and recreational fishers, results of considerable experimental fishing, and underwater observations (including our own at Penguin Bank). The many strikes at our hooks near the bottom (none during the short time of lowering and retrieving the line) indicate that species with the full range of diets were in an active feeding state at the bottom during much of the day and night.

Animals from all the major pelagic prey categories consumed (Table 3) have been reported at times in substantial quantities at depths where these snappers were collected. In many cases, these prey were reported to be near bottom (Struhsaker 1973; Wiebe et al. 1979; Kashkina 1986; Grassle and Morse-Porteous 1987; Bathmann 1988; Childress et al. 1989; Reid et al. 1991; L. P. Madin, Woods Hole Oceanographic Institution, personal communication). These reports (some from Hawaii) are consistent with a pattern of near-bottom feeding by snappers. However, all available evidence does not exclude the possibility that significant feeding occurs far above the bottom.

Regardless of the level in the water column where feeding occurs, it is clear that planktonic animals provide an important conduit for transferring production from lower trophic levels in the water column to some large snapper species. These snappers occupy a demersal habitat that does not seem to be highly productive. The planktonic subsidy from the water column, facilitated by vertical migration of the zooplankton, may be important in maintaining fishable stocks of these deepwater snappers.

### Spatial and Temporal Distribution

A baited hook does not represent a natural prey item for these snappers, but for the purpose of this study, an increase in CPUE was assumed to represent an increase in feeding activity. Diel cycles in feeding activity appear to be common and somewhat species-specific among the lutjanid snappers on Penguin Bank. Peak feeding of all these snappers as a group occurred during the morning and evening.

Nakamura (1967) and Shomura and Nakamura (1969), sampling with nets at depths of 60–200 m around the Hawaiian island of Oahu, reported marked increases in the abundance of zooplankton during early morning and evening. They observed strong diel fluctuations in abundance of ostracods, euphausids, pteropods, and larval fish, all of which are prey species for the zooplanktivorous snappers. Many zooplanktonic species migrate to surface waters at night to feed and return to deeper water during the day (Levinton 1982). This vertical migration could increase the availability of these prey to deepwater snappers during dawn and dusk as the zooplankton migrate past snappers occupying steep slopes or sites of high bottom relief.

The apparent diel distribution of zooplankton in the water column and the increased feeding activity by *Pristipomoides* species during early morning and evening suggest that these snappers are opportunistic zooplanktivores. However, pelagic urochordates, which were important in the diets of these snappers in our study, were less abundant than some of the other vertically migrating zooplanktonic groups in the net collections of Nakamura (1967) and Shomura and Nakamura (1969).

In general, the diets of the planktivorous *Pristipomoides* species had a higher percentage of thaliaceans at night and more pelagic crustaceans and fish during the day. This trend may reflect the difference in visibility of these prey and the role of vision in their capture. Small crustaceans and fishes would be more visible during the day, while the nearly transparent thaliaceans would be hard to see. At night, the relatively low visual acuity of the fish eye would result in much reduced ability to resolve smaller prey targets (Hobson 1991; McFarland 1991). However, many thaliaceans are bioluminescent, which along with their colonial habit could make them much more visible than small crustaceans or fishes. Their slow locomotion and bulky colonial form may make them more vulnerable to capture by random encounter in the dark.

Shomura and Nakamura (1969) reported that abundance of thaliaceans in Hawaiian waters was relatively low in summer and fall, higher in winter, and highest in spring. We found a similar trend in the abundance of thaliaceans in the diet of *P. filamentosus* on Penguin Bank. Kashkina (1986) reviewed a number of studies that reported high abundance of thaliaceans in portions of the "Hawaiian range" and elsewhere where there was upward mixing of nutrient-rich waters in spring. He suggested that such conditions stimulated planktonic production and provided food for increased thaliacean populations.

### *Resource Partitioning*

Some of the snapper species caught in our study exhibited considerable overlap in diel feeding schedules. However, niche overlap was probably minimized by partitioning of prey and peak feeding depth. Within the piscivorous guild, dietary overlap was high. However, these species seemed to be stratified by bottom depth of peak feeding activity (Figure 3B). Little niche dimension overlap was evident between *A. virescens* and the other members of the piscivorous guild (or other snappers), because *A. virescens* fed most actively during daylight and much higher in the water column than the other species. Potential overlap seems most likely between *E. carbunculus* and *P. zonatus*, as all three niche dimensions measured showed considerable overlap. However, we collected too few *P. zonatus* to permit estimating the degree of overlap with confidence. For the two strongly zooplanktivorous *Pristipomoides* species, both diets and diel feeding schedules overlapped considerably. However, peak feeding activity seemed to occur at a bottom depth about 50 m deeper for *P. sieboldii* than for *P. filamentosus*. Moderate overlap in all three measured niche dimensions seemed to occur between *P. filamentosus* and *P. zonatus*, but interpretation was difficult because of the small sample size of *P. zonatus*. Based on diet composition and depth and time of catch, strong niche overlap between the planktivorous and piscivorous guilds seems unlikely.

### *Fishery Implications*

Recent studies indicate that *P. filamentosus*, *E. coruscans*, and *E. carbunculus* have suffered significant growth overfishing around the main (inhabited) Hawaiian Islands and that *A. virescens* may have suffered some such effects (Ralston and Kawamoto 1988; Somerton and Kobayashi 1990a). Major reductions in spawning stock biomass of the first two species are raising concern among fisheries managers that they also may be experiencing recruitment overfishing (WPRFMC 1991).

Imposing size limits for retention of snappers has been suggested as a way to reduce the mortality of immature fish, increase the yield per recruit, and protect against recruitment overfishing (Somerton and Kobayashi 1990b). However, capture and release seems to result in high mortality, and the full benefits of a minimum size limit would be realized only if catches of undersize fish were minimized. This would be possible if undersize fish were naturally segregated from the larger fish by capture depth or time. However, the results presented here do not indicate that such stratification occurs. A possible approach to size-selective line fishing may be a judicious choice of hook size (Ralston 1990).

It seems unlikely that any foreseeable developments in gear or techniques will permit the fishery to harvest these stocks with high selectivity by species. However, our results are consistent with the reports of fishers that considerable selectivity can be achieved by choice of depth fished.

Population parameters and the ecology of individual species are often poorly known in tropical multispecies fisheries. Thus, groups of species such as deepwater snappers are sometimes analyzed and managed as a unit by approaches such as the total-biomass Schaefer model (TBSM) (Ralston and Polovina 1982). However, a thorough understanding of trophic relationships among the species making up the fishery is important for management of any multispecies fishery, and application of the TBSM may be inappropriate if such relationships remain unknown (May et al. 1979; Pauly 1979). The large differences in trophic roles of some of the snapper species at Penguin Bank suggest caution in lumping these species together in a TBSM analysis.

This study has not fully revealed the sources or production processes supporting these snapper populations. It is plausible that the productivity of the bank as a whole is enhanced by its hydrography. However, much of the food of these snapper species comes from pelagic (planktonic or nektonic) animals. This suggests that the occurrence and abundance of snappers on these grounds is not the result of some concentrated benthic food resource that is highly specific to localized bottom features. Bank features may provide some other localized resource (e.g., vertical relief, protective cover) that is important to snappers.

The distribution of these snappers may be affected by the upward deflection of deeper currents where the currents encounter the higher relief of banks, resulting in a higher local abundance of plankton (e.g., Brock and Chamberlain 1968). In an ecological study of the bottom fish resources of Johnston Atoll, Ralston et al. (1986) found *P. filamentosus* in much higher densities on the upcurrent side of the atoll than on the downcurrent side. They postulated that this was related to increased availability of allochthonous planktonic prey in the neritic upcurrent areas due to oceanic currents deflected by the atoll.

Although deepwater banks in Hawaii and the Pacific support highly productive fishery resources, their ecology remains relatively obscure. The results presented here are based on our collections from the south-central portion of Penguin Bank. These results provide a substantial contribution to knowledge of the trophic ecology of lutjanid snappers that support important deepwater fisheries on the bank and elsewhere throughout the Hawaiian Archipelago and other tropical seas.

## Acknowledgments

Major funding for this study was provided by the University of Hawaii Sea Grant College Program as project R/PB-2 of institutional grant NA85AA-D-SG082 from the National Oceanic and Atmospheric Administration (NOAA) Office of Sea Grant, Department of Commerce, and by state funding from the University of Hawaii. This is Sea Grant publication UNIHI-SEAGRANT-JC-93-16. Field support, including research vessel time, was generously provided by the National Marine Fisheries Service (NMFS), Honolulu Laboratory. Laboratory equipment, logistics, and administrative support were provided by the Hawaii Cooperative Fishery Research Unit (sponsored by the Hawaii Department of Land and Natural Resources, the University of Hawaii, and the U.S. Fish and Wildlife Service). We thank the captain and crew of the fishing vessel *Sea Verse II*, the officers and crew of the NOAA ship *Townsend Cromwell*, seagoing researchers of the NMFS Honolulu Laboratory, and student volunteers for their assistance in fishing operations. J. Hirota, E. A. Kay, J. E. Randall, S. B. Reid, M. P. Seki, and R. E. Young were helpful in identifying prey specimens. R. Kokubun provided the necessary statistics on fishery landings from the data base of the Hawaii Division of Aquatic Resources. R. E. Brock, T. A. Clarke, E. E. DeMartini, and R. B. Moffitt provided helpful comments on the manuscript.

## Appendix: Diets of Deepwater Snappers

TABLE A.1.—Diets of six deepwater snapper species collected at Penguin Bank, Hawaii, in 1987–1989. Shown are the percentages of predator individuals that consumed each prey (*F*), the percentages of all numbers (*N*) and volume (*V*) provided by each prey, and each prey's index of relative importance (IRI) in gut contents. The number of guts with any identifiable contents is indicated beside each snapper species in parentheses. Prey categories followed by an asterisk are also included in the larger ecological category "Pelagic small Crustacea." Values for the highest systematic levels are underlined. Values of IRI were calculated separately for each prey category (line entry); values may be compared across categories at comparable systematic levels.

| Prey category | Percent frequency (*F*) | Percent number (*N*) | Percent volume (*V*) | IRI |
|---|---|---|---|---|
| | | ***Pristipomoides sieboldii* (60)** | | |
| Fish (all)[a] | 21.7 | 1.4 | 22.8 | 527.4 |
| Fish (juvenile and adult) | 10.0 | 0.4 | 21.2 | 216.7 |
| Congridae | | | | |

# The Western Pacific Fishery Information Network: A Fisheries Information System

DAVID C. HAMM

David C. Hamm is with the Honolulu Laboratory, Southwest Fisheries Science Center, National Marine Fisheries Service, NOAA, 2570 Dole Street, Honolulu, HI 96822-2396.

*ABSTRACT—The Western Pacific Fishery Information Network (WPACFIN) is an intergovernmental agency cooperative program sponsored by the National Marine Fisheries Service (NMFS) to help participating island fisheries agencies carry out data collection, analysis, reporting programs, and data management activities to better support fisheries management under the Magnuson Fishery Conservation and Management Act; and to help meet local fisheries information and management needs. The WPACFIN is the central source of information for Federal fisheries management of most fisheries in American Samoa, Guam, and the Northern Mariana Islands, and it plays an important role in acquiring fisheries data in Hawaii. This paper describes the development and status of this fishery information system.*

### Introduction

Fisheries in the Pacific have been rapidly changing during the 1980's, and fisheries agencies have been changing with them to obtain and utilize the proper data and information needed to monitor and manage the resources under their jurisdictions. To help meet the ever growing and changing information needs of fishery agencies of the Pacific, the National Marine Fisheries Service (NMFS) established a Pacific Fishery Information Network (PACFIN) for the western coastal states and Idaho, and the Western Pacific Fishery Information Network (WPACFIN) for the U.S.-affiliated fishery agencies in the central and western Pacific island areas of American Samoa, Hawaii, Guam, and the Northern Mariana Islands. This paper is exclusively concerned with WPACFIN.

Through the NMFS WPACFIN program, an organization of cooperating island fisheries agencies has developed a network to share data, information, and technology to improve fisheries management under the Magnuson Fishery Conservation and Management Act and to meet local fisheries management needs. The voluntary and cooperative nature of the network cannot be overemphasized, for these attributes are the backbone of the existence of the system. The information available through WPACFIN has been developed through cooperative efforts of the participating agencies to improve their data collection, compilation, computerization, and summarization capabilities by means of technical assistance provided by the central WPACFIN program at the Honolulu Laboratory and by means of financial assistance from various NMFS and other funding sources.

From the beginning, it has been the philosophy and policy of the WPACFIN program to adopt the general NMFS policy of building upon local fisheries office expertise and capabilities as a means of improving Federal fishery management capabilities. The WPACFIN system embodies the general principles of a Federal and state partnership and a symbiotic relationship in collecting, processing, analyzing, sharing, and managing fisheries data, and builds upon the history of cooperation among agencies. From the standpoint of the NMFS, the overall functional goal of the WPACFIN system is to provide quality fisheries data needed to develop, implement, evaluate, and amend Federal fishery management plans (FMP's) for the western Pacific region. The information needed to manage Federal fisheries under MFCMA should be a composite subset of information required by fully functional local fisheries agencies. Therefore, the operating philosophy of the central WPACFIN office in working with island agencies has been to assist them in becoming fully functional in obtaining and providing data and information needed to meet both Federal and local fishery management needs. By building upon the capabilities of local agencies, efficiency, benefits, functionality, and data availability can be maximized while overall costs and duplication of effort can be minimized. Accomplishing this requires significant levels of commitment on both sides and a common goal for improved fisheries management.

### The WPACFIN system

The use of the term WPACFIN is sometimes confusing because it can be used to refer to any of the three distinct but interrelated major aspects of the system that are embodied in the concept of a cooperative fishery information network, or it can refer to the "system" as a whole. The three aspects of the WPACFIN system are its 1) organization, 2) program, and 3) network. These are all intertwined and inseparable as far as the functionality of the WPACFIN system is concerned.

The WPACFIN organization refers to the combination of participating agencies and how they interact to make decisions and recommendations for improving fishery management capabilities in the region. The participating agencies of WPACFIN (Fig. 1) include the Western Pacific Regional Fishery Management Council (WPRFMC or Council), the American Samoa Department of Marine and Wildlife Resources (DMWR), the Commonwealth of the Northern Mariana Islands' Division of Fish and Wildlife (DFW), the Guam Division of Aquatic and Wildlife Resources (DAWR) and Department of Commerce (DOC), the Hawaii Division of Aquatic Resources (HDAR), and the Honolulu Laboratory and Pacific Area Office of the NMFS. For simplicity, this paper will refer to the island fisheries offices not based in Hawaii as the "flag state" agencies.

To help coordinate all the participating agencies and to help set goals and priorities for meeting the information needs through WPACFIN, a committee composed of all the heads of the participating fisheries agencies was established in 1982. This committee was originally named the WPACFIN Data Goals Committee, but was later renamed the WPACFIN Fisheries Data Coordinating Committee (FDCC). The FDCC is the advisory body within the WPACFIN organization. The intent of the committee is to ensure that all required data are available to each participating agency and to the Western Pacific Regional Fishery Management Council, its Plan Monitoring Teams, its Scientific and Statistical Committee, and fishery managers, in a form, quality, and time frame necessary to meet their respective fisheries management responsibilities. Specifically stated, the purposes of the WPACFIN FDCC are to:

1) Provide a forum for a regional exchange of ideas about fisheries data and for meeting local and regional fishery management goals;

2) Establish WPACFIN activities and priorities and recommend improvements in efficiency, effectiveness, and timeliness of data collecting and processing activities;

3) Develop and coordinate a WPACFIN Fisheries Data Plan for implementation in each member area;

4) Promote the development and implementation of data collection, storage, and transfer standards to facilitate merging data into WPACFIN; and

5) Designate membership of a Technical Subcommittee and coordinate the Subcommittee's work on technical aspects of implementing WPACFIN.

The FDCC also established guidelines for the proper exchange and use

of fishery data and for safeguarding the confidentiality of data submitted by member agencies:

1) WPACFIN will not release confidential data in any format without specific written permission from the agency contributing the data to the system.

2) Requests for raw (nonsummary) data or requests from nonmember agencies will be referred to the donor agency.

3) If access is granted by the donor agency, WPACFIN may provide the data directly to the user from the central system at the donor agency's request.

4) Confidential data submitted to WPACFIN are generally available for NMFS employees to use provided the employee has signed a Statement of Nondisclosure and has a "need-to-know" as defined in NOAA Directive 88–30.

5) Summary and nonconfidential data in WPACFIN are available to all users without obtaining donor agency approval.

6) Specific restrictions may be placed on sensitive data sets submitted to WPACFIN that could limit access to users identified by the donor agency.

The WPACFIN program is a task within the Fishery Data Management Program of the NMFS Honolulu Laboratory's Fishery Management and Performance Investigation. It was established in 1981 to be the nucleus for organizing, implementing, and maintaining the fisheries information network in the western Pacific. The WPACFIN program is headed by the leader of the Fishery Data Management Program, and its staff has expertise in computer systems design, fisheries biology, and computer programming. The types of support offered by the WPACFIN program cover a variety of administrative and technical activities. Because of differences in data collecting and processing systems, political atmosphere, personnel, and level of commitment to upgrade and change, the flag state agencies have been the major focus of implementing the WPACFIN system, and they have been the major users of support offered by the WPACFIN program. Description of some of the major WPACFIN program support activities follows.

1) Administrative support has been provided at all levels for overseeing the WPACFIN program management, budgeting, and planning activities, such as developing and implementing "memoranda of understanding" and data sharing agreements between NMFS and participating agencies, and coordinating meetings of the FDCC and its Technical Subcommittee.

2) Technical hardware and software support has been crucial to developing local expertise.

3) System and survey designs have been studied in all areas, either by using consultant contracts or in-house NMFS expertise and resources (CIC Research, Inc.[1, 2], Omnitrak Research and Marketing Group, Inc.[3], and Malvestuto[4]).

4) Data base management and data processing systems have been established for many data systems such as commercial landings, offshore and inshore creel surveys, tuna transshipment, tournament sampling, vessel inventory, and fishery imports. Integrated, menu-driven, user-friendly, data base management systems have been developed and programmed to meet the needs of island agencies.

5) A wide range of training support has been provided to island agencies including on-site and central training workshops on microcomputer hardware and software, data base and file management, data quality control procedures, data collecting, forms design, and detailed training on implementing the data processing applications.

6) Fisheries data bases provided to the system by participating agencies are maintained at the central WPACFIN program office. Direct online access to some of these centralized data bases is a long-range goal.

7) Numerous report generation and data analysis activities, such as filling ad-hoc data requests, assisting in producing the flag state agencies' report modules for the annual bottomfish and pelagics plan monitoring teams (Hamm and Quach[5]; Hamm et al.[6, 7]), and producing the annual catch and effort report series "Fishery Statistics of the Western Pacific" (Hamm et al., var. years[8]).

In addition to providing these support functions to the official WPACFIN agencies, the central WPACFIN program office has provided similar technical guidance and assistance to fisheries offices in other U.S. affiliated Pacific island areas such as the Federated States of Micronesia (Pohnpei, Kosrae, Chuuk, and Yap) and the Republic of Palau, but on a more limited basis. Notwithstanding the limited support provided, at least some "WPACFIN-compatible" data systems have been created in each of these other island areas.

The WPACFIN network refers to the technologies, activities, and meth-

odologies upon which the system functions, including all the hardware, software, communication links, data sharing capabilities, and the data bases themselves. The network is the backbone of WPACFIN, and is a physical part of each participating agency. In general, the network is a microcomputer-based means of sharing data and information among fisheries agencies to support fisheries management needs via mail and direct telecommunications. It is more fully described under the WPACFIN evolution section of this paper.

Together, these three aspects of WPACFIN, the organization, program, and network, make the WPACFIN system what it is, a combination of agencies working together in a voluntary and cooperative manner to improve fishery management capabilities in the central and western Pacific region.

## Problems and Challenges of Implementing WPACFIN

Implementing an information network among the U.S. affiliated islands of the Pacific required resolving some challenging problems and operating within certain strict limitations. Effective communication is important in any cooperative undertaking, but it is critical in a task such as developing and implementing WPACFIN. The first, and possibly most obvious obstacle limiting communication among participating agencies is the physical size of the area involved. The distances between the central WPACFIN office and the flag state agencies are great, and the Exclusive Economic Zones (EEZ's) are the largest under jurisdiction of any of the Councils, totaling over two million square miles (Fig. 2). To put the size of the area in perspective, if the central WPACFIN office was in Bangor, Maine, the American Samoa fisheries office would be in Venezuela and the Guam and Saipan offices would still be in the Pacific Ocean well west of California. The distances make costs of on-site visits high, and communication via telephone lines is also quite expensive; thus, overcoming the complications caused by the distances involved was no minor task, but progress was steadily made because of the high level of cooperation and commitment by the flag state agencies. On-site visits to the flag state agencies by central WPACFIN technical staff were well planned and always productive by concentrating a lot of activity into the few days available.

Cultural differences represent a second challenge in communication that is also somewhat related to the size of the area covered. The Samoan, Hawai-

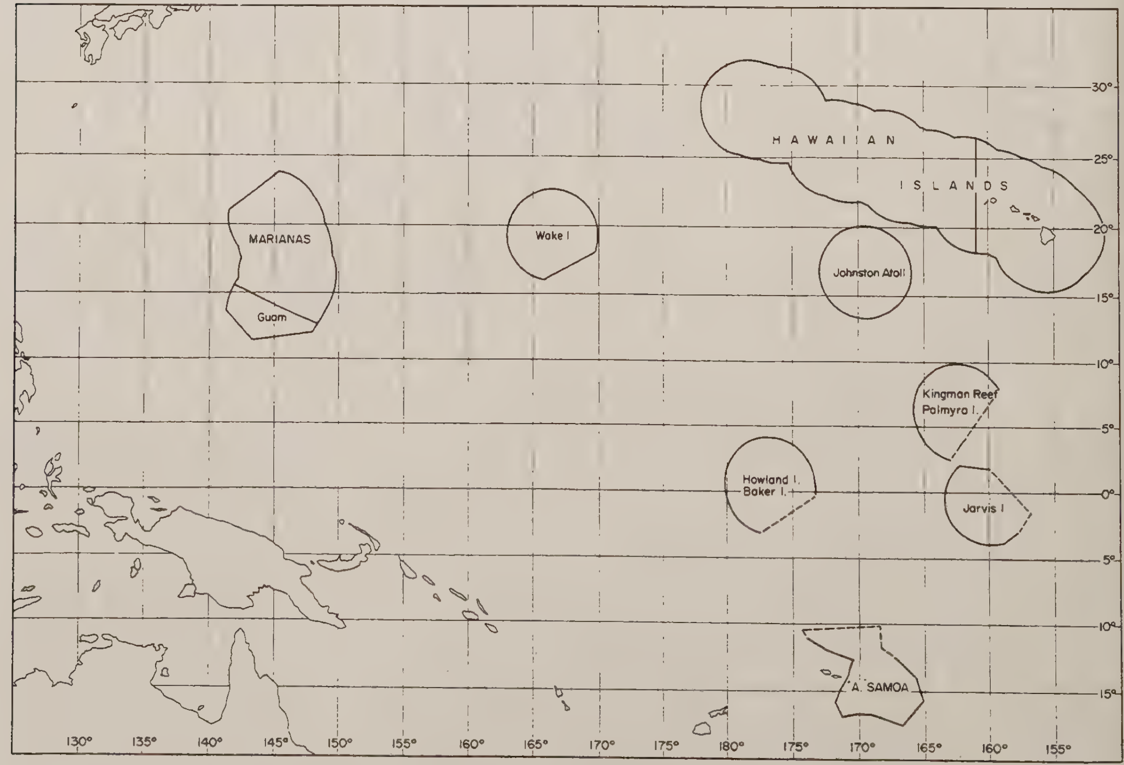

Figure 2.—Boundaries of the Fishery Conservation Zone around Hawaii, American Samoa, Guam, the Northern Mariana Islands, and other U.S. possessions.

ian, and Chamorro/Carolinian cultures are all quite different; even within the Chamorro/Carolinian cultures of Guam and the CNMI, differences exist between islands. Overcoming communication problems and understanding limitations related to cultural differences require sensitivity to and respect for local customs, preferences, inhibitions, attitudes, and sometimes underlying and significant prejudices. It requires time to build relationships, gain confidences, and understand the differences and nuances of each island culture. Not understanding or ignoring cultural differences reduces the effectiveness of communication and is likely to result in less functional and useful data systems. The WPACFIN philosophy embodies these cultural differences as much as possible in developing new or modifying existing data systems. Related to the cultural differences are political differences and stages of development of the bureaucracies of the island fisheries agencies; these too must be considered and overcome.

Several other complications in developing an automated fishery information network in the Pacific may be broadly categorized as infrastructure problems. In 1981, only the State of Hawaii possessed laws requiring the reporting of fisheries statistics. Therefore, historical data for the early years of most island fisheries were inadequate, as was available funding; voluntary reprogramming of available funds by the flag state agencies made implementing data system changes possible. Progress was also hindered by a lack of adequate staff. Fisheries and computer professionals are still very scarce in the Pacific, so the central WPACFIN office has had to provide nearly all computer training and programming support, at least to the flag state agencies. The American Samoa and CNMI offices rely almost exclusively on contract professional biologists from the U.S. mainland. As a result, a high level of turnover, low level of stability in programs, and a poor understanding of the history of the fisheries exist. The WPACFIN program has worked to help the island agencies overcome these problems.

The last noteworthy challenge in implementing and upgrading WPACFIN has been the dynamics of rapid changes in the fisheries, the data needs, and the computer technologies over the past decade. In the early years, fisheries managers required only a few summary tables and enough basic data to categorize the fisheries and document their importance for justifying and implementing fishery management plans. Now, more detailed annual reports are required that document status of the stocks aspects of fishery performance, and selected economic indicators. Fortunately, computer technology capable of handling the increased data and analytical needs has also expanded, but with the expansion has come a challenge of maintaining stability of systems while implementing significant improvements. This has been accomplished successfully in the flag state agencies where levels of cooperation were high and levels of bureaucracy and changes in the basic fisheries were fairly low, but less successfully in Hawaii where the reverse is true.

## WPACFIN Evolution

The discussion of the evolution of the WPACFIN system will be divided into the same three aspects of WPACFIN as previously described, the organization, program, and network.

The original members of the WPACFIN organization included all those shown in Figure 1, except the Guam Department of Commerce, which joined in August 1988. Initially, HDAR participation in the FDCC was self-limited to observer status, but in December 1984, with completion of the Hawaii statistical system study (DLNR[9]), they became a full voting member of the FDCC. The FDCC held ten meetings from 1982 to 1989 which mostly dealt with issues such as establishing memoranda of understanding and data share agreements, developing guidelines for operating the FDCC, implementing the first and second generation systems, and seeking additional funding to support the network. From 1989 to 1992, the FDCC met eight more times and concentrated its efforts on defining projects and objectives under the new PACFIN initiative, developing a long-term data plan for the Pacific, and redefining the functions, services, and data bases the future WPACFIN system should include. The FDCC's Technical Subcommittee has held several workshops and training sessions and has developed standard guidelines for data quality control and file management procedures to be used by each member agency in developing their own specific procedures to insure that only quality data enter the central WPACFIN files.

The WPACFIN program has been crucial to WPACFIN system development. Established in 1981 by the Southwest Fisheries Center as a separate task within the Honolulu Laboratory, it was initially staffed with one full-time computer systems analyst. Staff size and expertise expanded to improve WPACFIN capabilities in meeting overall fishery information and Council-related needs. Expertise in fisheries biology was transferred into WPACFIN to help with fisheries applications and analyses.

Discussion of the evolution of the WPACFIN network will be limited to the major hardware and software used and will be described in three sections, pre-WPACFIN, first generation WPACFIN, and second generation WPACFIN. Identification of the data bases maintained within the network is found in the next section.

The pre-WPACFIN situation was a fairly unstructured, low technology environment involving no computer use outside Hawaii. Fishery statistics in the flag states were computed by hand or sometimes with the use of desktop calculators. Data collecting systems, where they existed, were fairly rudimentary and typically were not based on valid statistical designs. Data processing at HDAR and the Honolulu Laboratory was performed by keypunch cards, batch processing, and limited time-share processing on state-operated IBM mainframe computers. Data exchanges were limited to periodic transfer of computer tapes from HDAR to the Honolulu Laboratory. The HDAR had over a two-year backlog of data to process.

---

[9] Div. Aquatic Resources, State of Hawaii. 1984. Hawaii fisheries statistics system design study. Division of Aquatic Resources, Div. Land and Natl. Resources, 214 p.

The initial steps in implementing the first-generation WPACFIN system consisted of installing a two-station, key-to-disk data entry system at the Honolulu Laboratory and Apple II+ microcomputer systems in each of the original four participating island agency main offices plus central WPACFIN. These Apples were the first microcomputers introduced into any of the flag state agencies. The original off-the-shelf software included a highly structured, but somewhat limited, data base management system capable of all processing steps from data entry through report generation, a spreadsheet system, some rudimentary graphics and statistics packages, word processing, and some basic utilities. By the end of 1982 all island systems had been installed, basic training provided, and data bases established for the major fishery monitoring systems (Hamm[10]). Over the next several years, hardware and software upgrades continued to be made which included additional computers, networked hard drive units in two offices, and extensive custom-programmed processing systems for newly designed and implemented creel survey sampling programs in all flag state areas (Hamm[11]). Additional data bases and improved sampling programs were established in all flag state areas to monitor the resources better. The HDAR began reducing the backlog of landings reports and completed the WPACFIN-funded "Hawaii fisheries statistics system design study" (1984). Some of the newly designed sampling programs for the flag states (e.g., market sampling, size frequency and biological sampling, some creel surveys) were never implemented or were soon terminated because of lack of funds to conduct the work or because of a lack of demonstrated and reinforced need for these data for federal management purposes. This proved to be most unfortunate as these types of baseline data were later needed by Council Plan Monitoring Teams.

In addition to the Apple II+ hardware for processing centrally stored files, the first generation central WPACFIN hardware environment initially included a time-share link to a PDP 1170 minicomputer. However, the availability of the minicomputer proved to be short-lived, and the Laboratory obtained an in-house CPM-based multiuser-multiprocessor super-microcomputer with over 40 workstations which became the central computer for some WPACFIN applications. This fairly simple first-generation processing environment continued to meet data processing needs into the mid-1980's when it became apparent that a major switch to more modern and powerful processing equipment would soon be needed to meet the ever increasing federal requirements for more sophisticated analysis and reporting.

The evolution to second-generation WPACFIN processing systems began with the microcomputer boom of the mid-1980's.

Whereas most of the first-generation hardware and software systems were provided through central WPACFIN technical and financial support, the evolution to second-generation WPACFIN processing systems required much more financial commitment from the other participating agencies. This was partly accomplished through reprogramming existing Federal grant funds which had already been extensively used to implement improvements in data collecting systems, and partly through the use of other Federal and local funds. The new WPACFIN standard operating environment centered around the IBM-compatible MS-DOS microcomputer and the dBASE data base management system. The microcomputer revolution soon reached all participating agencies, and they began expanding their use of computers beyond their fisheries data sections to their fisheries biologists, and wildlife and administrative sections. The American Samoa DMWR, CNMI DFW, and Guam DOC offices followed the WPACFIN standard almost exclusively in their expansion efforts, but the Guam DAWR office chose to use the Apple Macintosh system and the HDAR office expanded in several directions simultaneously: into direct use of the IBM mainframe, a newly installed State WANGNET minicomputer system, and into increased use of both Macintosh and IBM-compatible microcomputers.

During the evolution to second-generation computer systems, the major emphasis of the central WPACFIN program was to support the conversion to the new IBM-compatible operating environment by assisting with purchases of hardware and software and by developing much more sophisticated and comprehensive, user-friendly, menu-driven dBASE applications for an increasing number of data collection and analysis systems. The most recent phases of implementing the second generation WPACFIN system include establishing direct computer-to-computer telecommunications links between the central office and all other agencies, and creating an on-line central system for dial-in access to principal island data sets. The evolution into the second-generation operating environment is continuing. As all the basic fisheries data systems become fully functional in the new operating environment, more emphasis will be placed on developing more integrated data systems and additional analysis, assessment, and reporting systems to enhance fisheries monitoring and management.

## Current Data Systems

NMFS and each of the four island areas have a variety of data bases and associated collecting and processing systems to facilitate fisheries monitoring and management activities (Table 1), but it is beyond the scope of this paper to document them fully. Each fishery, island agency, and data processing system has its own needs, peculiarities, uses, capabilities, and limitations that make it unique. In general, each agency is responsible for ensuring its data are as accurate as possible before sharing files through the central WPACFIN office. Most data collected by participating island agencies are centrally archived for ready access and data sharing in WPACFIN files at the Honolulu Laboratory. Most data collected by NMFS are maintained at the Honolulu Laboratory by the Fishery Management and Performance Investigation to reduce WPACFIN storage requirements. Not all data are readily available to all users because of confidentiality or sensitivity considerations, or because use of the data is local rather than regional.

From a fisheries monitoring perspective, the most important systems in each island area are the commercial landings, creel survey, and logbook systems. Even though these systems vary significantly in design and degree of implementation from island to island and from system to system (e.g., voluntary vs. mandatory, on-site vs. mail-in, census vs. sample, and local agency vs. central WPACFIN sponsored), they provide the basis for monitoring fisheries of the area. The other data systems operated by fisheries agencies provide important validation cross-checks, biological status, augmentary, and ancillary information on the resources and fisheries exploiting them.

## Future Goals of the WPACFIN System

During the past 11 years, significant progress has been made toward meeting fisheries management needs in each of the Pacific island areas under the Council's jurisdiction; however, much more remains to be done. Fisheries management information requirements continue to change, and significant data and information gaps still exist. Filling those gaps will require some reorientation of major activities within the WPACFIN system to implement further improvements in the methods of data collection, processing, analysis, and reporting. Some of the goals of the WPACFIN system for future activities are the following:

1) Analyze existing data systems to document information gaps.

2) Establish additional data collecting, processing, and analyzing standards, and implement changes required to meet those standards.

3) Implement computer-based telecommunications between all participating agencies to facilitate data exchange and system upgrades.

4) Establish dial-in access to centrally archived data bases.

5) Establish integrated central data bases and create a sophisticated query system to improve access to and use of available data.

6) Develop new and improved fisheries assessment and analysis systems to increase the reliability of information used in the fishery management decision making process.

7) Encourage further state and Federal cooperative efforts in meeting fishery management objectives in the western Pacific.

## Summary

Over the past 11 years the NMFS's WPACFIN program has assisted island fisheries agencies in advancing from nonexistent or rudimentary manual data systems to sophisticated computerized systems capable of providing useful fisheries monitoring and analysis information on a timely basis. Through the cooperative efforts of all participating agencies, the WPACFIN system has become the common thread that weaves the member agencies together through sharing data and information about the fisheries of the Pacific in their efforts to protect and manage these resources.

Several critical factors have been identified which influence the level of success obtainable in implementing a complex, intergovernmental, voluntary, and cooperative project such as this fishery information network:

1) Commitment and ability of agencies to implement changes and provide resources to accomplish change.

2) Long-term commitment and quality of individual employees involved in the project, especially those involved in project management.

3) Consideration of local needs, culture, politics, capabilities, limitations, and personnel.

4) Continual contact, support, feedback, and training.

As fisheries change and fisheries management needs grow in complexity and diversity, so must the resolve of the participating agencies grow to meet the new challenges. The most important factor influencing the future of the fisheries of the Pacific will continue to be the desire and the ability of the many agencies to work together to become a unified force in meeting the challenges of rational and effective fisheries management. It is the long-term goal of the WPACFIN system to assist in making effective management a reality. The WPACFIN system continues to evolve to meet needs of rapidly changing fisheries management requirements.

## ABSTRACT

California's drift gill net fishery developed rapidly in the late 1970s off southern California. The fishery originally targeted the common thresher *Alopias vulpinus*. Almost immediately swordfish *Xiphias gladius* and shortfin mako *Isurus oxyrinchus* became important components of the catch.

We examined and summarized data obtained from the California logbook system, landing receipts, and market samples taken from this fishery over the 10 fishing seasons from 1981-82 through 1990-91. During this period the fishery evolved from a small nearshore experiment to a major California fishery. Significant changes in nearly every aspect of the fishery occurred including boats and gear, techniques and regulations, fishing areas and seasons, and targeted species. These data form a base line from which changes in the fishery and harvested stocks can be compared in the future.

The drift gill net fishery operates primarily in the area between San Diego and Cape Mendocino and concentrates much of its effort on swordfish in the Southern California Bight during the months of May to December. During the period studied, fishing effort decreased 50% to 60%, from highs of approximately 11,000 sets to a low of about 4000 sets in the 1990-91 season. This decrease in effort corresponds to a decrease in total landings of approximately the same proportions. Decreases in landings of common thresher were over 80%, while swordfish and shortfin mako landings decreased 60% and 40% respectively. Average sizes of swordfish showed no change during the 1981-82 to 1990-91 fishing seasons. Average sizes of shortfin makos showed a decrease of approximately 40% from the 1982-83 through the 1985-86 fishing season, but rebounded during the 1989-90 season to within 15% of the 1982-83 season. Average sizes of common thresher, however, decreased 30% from the 1982-83 season and remained low. This may indicate a decline in the common thresher stock or reflect changes in the season and area of fishing operations.

A number of problems and conflicts occurred during the first 10 years of the fishery (e.g. bycatch of marine mammals and striped marlin *Tetrapturus audax*) which were resolved for the most part through the cooperative efforts of the commercial industry, the sport industry, environmental groups, and State and Federal governments. The incidental catch of marine mammals is apparently low and not compromising any stocks, although the potential for damage remains and therefore monitoring is prudent. Bycatch of other fishes does not appear to be a problem except for the catch of blue sharks *Prionace glauca*, which has an unknown affect on local stocks.

# INTRODUCTION

California's drift gill net fishery for pelagic sharks and swordfish *Xiphias gladius* developed in the late 1970s off southern California. The initial concept of catching large pelagic sharks was inspired by the occasional catch of sharks in gill nets used to drift near shore for California barracuda *Sphyraena argentea* and white seabass *Atractoscion nobilis*. The fishery evolved rapidly as fishermen modified coastal gill nets and techniques for catching white seabass, sharks, California halibut *Paralichthys californicus*, and California flyingfish *Cypselurus californicus*.

The successful development of the drift gill net fishery might be attributed to greater fuel efficiency than in some other fisheries, pelagic shark resource abundance, consumer acceptance of shark as a food fish, and the perseverance of fishermen pursuing a new source of livelihood. As fishing techniques and gear improved, market demand for sharks increased, and in less than 5 years the number of drift gill net permits grew to over 200. These shark fishermen soon discovered that the nets were also efficient at catching swordfish, worth nearly four times the dockside value of sharks (Bedford 1987; Holts 1988). The value of swordfish and market demand for the high quality, relatively inexpensive sharks encouraged further development; fishermen started exploring new areas farther offshore and northward off Oregon and Washington.

As the fishery expanded, conflicts emerged with the commercial harpoon fishery for swordfish and with the recreational hook-and-line fishery for striped marlin *Tetrapturus audax* and swordfish, though few swordfish were caught by hook and line. Commercial harpoon fishermen and recreational fishermen feared reduced availability of swordfish and striped marlin. Additionally, striped marlin were specifically reserved for the recreational fishery and could not be sold even if caught incidentally. Another bycatch problem that developed was the incidental catch of marine mammals (Hanan and Scholl 1985; Diamond et al. 1986, 1987), especially California sea lions *Zalophus californianus*, which were caught in large numbers in drift gill nets near the Channel Islands. Because of these conflicts, concern for the targeted fish resources (Hanan 1984), and the fact that very little was known about the population status or biology of thresher sharks *Alopias* spp. (Berkson 1985), the Legislature enacted a series of laws regulating the new fishery (Bedford 1987).

In this bulletin, we review the first 10 years of the California drift gill net fishery, including a fishery description, catch and fishing-effort summaries, regulations, and biological summaries.

# THE FISHERY

The drift gill net fishery originally targeted common thresher *Alopias vulpinus* and shortfin mako *Isurus oxyrinchus* (locally known as bonito shark). Almost immediately swordfish became an important component of the catch. Additionally, some other unexpected or previously considered rare species were caught. These included two other thresher shark species, bigeye thresher *A. superciliosus* and pelagic thresher *A. pelagicus*[1]. Fishermen and fish buyers learned what was marketable and in some cases developed markets for fishes not previously available in commercial quantities (e.g. opah *Lampris guttatus* and louvar *Luvarus imperialis*). The bycatch of nontarget fishes varied by year, but some of the more predictable and saleable bycatches were albacore *Thunnus alalunga* and other tunas, Pacific bonito *Sarda chiliensis*, and white seabass (Table 1).

During the period reviewed, primary ports for the drift gill net vessels were San Diego, San Pedro, and Santa Barbara; additionally, some boats utilized Dana Point, Port Hueneme, Ventura, Port San Luis, Morro Bay, Monterey, Moss Landing, and San Francisco Bay area ports. Depending on where they were fishing, drift gill net boats landed fish at all of these ports as well as several others.

Fish availability, market price, weather conditions, vessel fishing range, and fish-cooling capabilities dictated the length of fishing trips. Drift gill net trips ranged from one night to one month and total trips per year varied widely by skipper. Some skippers made only short trips while others remained at sea 2 to 3 weeks or more (Diamond et al. 1986). After extended trips or when catch rates were low, fishermen often docked at ports other than their home port to allow for shore leave or to wait for improved fishing conditions. Often they were gone from home port several months, returning only to change fishing gear for the opening of a different fishery.

Areas of operation for the drift gill net fishery were the nearshore banks, canyons, and escarpments near the offshore islands (water depths ranged from 400 to 1000 fathoms [fm]; Figures 1 and 2). Gradually, as the fishery matured and larger vessels entered the fishery, operations moved offshore and northward to the more distant seamounts and to the edge of the continental shelf. During and among fishing seasons, fishing areas shifted depending on availability of targeted fish and legislated time and area closures. Fishing effort varied from season to season and peaked in the mid-1980s (Figure 3).

---

[1] *Although this species has not been previously reported in California waters, three California Department of Fish and Game observers including one of the authors (Hanan) identified this species in the observed catch. Pelagic threshers were also reported and measured by CDFG samplers at the docks as the sharks were offloaded. Unfortunately, no specimens were photographed or retained.*

Using radios, some fishermen communicated in coded messages with other members of loosely formed organizations called "code groups." They shared location information and presence or absence of desired fish. When catch rates were low, code-group members spread throughout the fishing range in search of fish and kept each other informed of fishing conditions, catch rates, and other pertinent information. Often, fishing vessels moved rapidly from one area to another based on information from their code group.

Because of competition for available fish and code-group loyalty, airplanes were hired to observe catches of other code groups. To counter this spy tactic, fishermen sometimes covered their catch with tarps or created fake fish by leaving a fish head protruding from under a tarp. Sometimes pilots would throttle back their engines and glide over a fishing boat in hopes of covertly gaining information.

In the first few years of the fishery, most of the fishing vessels were wooden or fiberglass; gradually there was a transition to steel or aluminum as the fishery developed. Vessel size ranged from 30 to 75 ft. Average vessel size increased with time, especially for those fishing farther offshore and northward. Fish holds were generally below decks and capacity varied depending on boat size and configuration. Fish-cooling capabilities varied widely from none to ice, brine spray, or refrigeration.

Crew size ranged from one to six. Crew members were compensated usually with a share of the catch proceeds or sometimes with cash wages. When shares were used as compensation, often they were split in some combination of the following: a share to the owner, a share to the skipper, a share or shares to the boat (for food, fuel, and other overhead), a share for each crew member, and sometimes one for the permit holder, who may or may not have been one of the aforementioned.

Drift gill net permits were issued to individual fishermen rather than to boats; thus the value of boats did not become artificially inflated, and permit holders could buy new boats as needed. Because of a requirement that a permit holder be onboard during fishing operations, some permit holders would "hire out" (ride for cash or a share) on other fishing vessels for skippers who did not have a permit. The practice of hiring out was eliminated in 1980 by requiring permit applicants to declare on which fishing vessel they would be using the permit. Also in 1980, the legislature made the drift gill net fishery a limited entry fishery, setting a maximum number of permits and allowing those already involved to continue fishing. The number of drift gill net vessels may have been as high as 300 in 1985, but there were rarely more than 100 active vessels during any of the fishing seasons described here.

TABLE 1. Landings (lb) by California drift gill net vessels during the 1981-82 through 1990-91 fishing seasons, compiled from landing receipts. Data for 1990-91 are preliminary. Some landings reported here are of species (i.e. angel sharks) not usually caught by drift gill net vessels, but have been included because they were reported on landing receipts.

[a] *The occurence of some of these species within the range of the California drift gill net fishery is unconfirmed. Published landing figures (Oliphant et al. 1990) have included several of these species under "Sharks, miscellaneous" or, in the case of pelagic thresher, under "Shark, common thresher."*

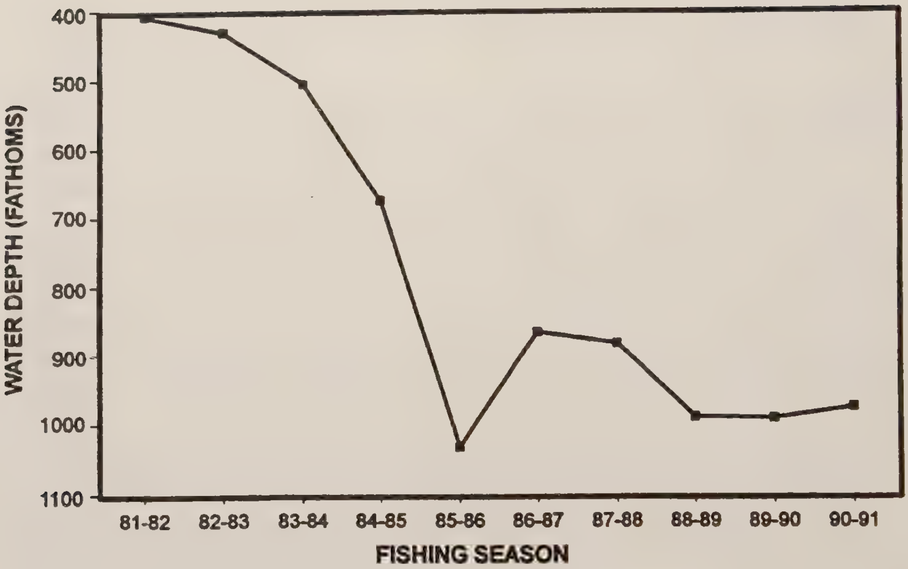

FIGURE 1. Average water depths (fathoms) fished by California drift gill net vessels for the 1981-82 through 1990-91 fishing seasons.

There was some illegal fishing (e.g. fishing without permits, use of excessively long nets, and other violations), but the value of the vessels and gear, combined with an active state enforcement program and costly penalties (e.g. the boat, net, and/or catch were subject to seizure and sale by court order upon conviction), discouraged the more blatant illegal activities.

## Gear and Fishing Operations

The visual characteristics of this fleet were distinctive. Often, 50 or more vessels fished within several miles of each other and at night could be identified by their bobbing, weaving mast lights. During the day they were more difficult to locate, but once sighted they were striking with the large net reel behind the cabin, the metal net or propeller guards raised above the stern, and the colorful bumper-ball floats stored along the wheelhouse (Figure 4). The net guards had the look of a large baseball catcher's mask or the face guard on a football helmet. Most drift gill net vessels employed a hydraulic or electric winch and boom for lifting the catch into or out of the hold and occasionally to assist in bringing aboard large fish.

Some skippers had previously harpooned swordfish and when issued a drift gill net permit were called dual permittees. In addition to net gear, their vessels

had wooden or metal planks extending 10 to 15 ft beyond the bow ending in a bow pulpit. Fishermen harpooned swordfish from the pulpit using harpoons tipped with a metal dart ("lily iron") designed to detach from the harpoon after striking the fish. The dart was attached by a line to large floats, and after striking a fish, the floats were released to tire the fish and keep it at the surface for later retrieval. Some vessels had a crow's nest high above the deck from which a fisherman could spot fish, direct the harpooner, and often steer the boat (Bedford and Hagerman 1983).

Nets used in the drift gill net fishery (Figure 5) ranged from 800 to 1000 fm in length. They were constructed of 3-strand, #24 to #30 twisted nylon tied to form meshes. The net was attached to the float line by means of a hanging line laced through two to four meshes of the top of the net and tied at intervals of 8 to 24 inches along the float line (Figure 5 detail). The number of meshes per hanging determined the amount of slack or tautness of the net and varied widely among skippers. The number of meshes between the cork and lead lines (depth of net) varied from 50 to 100 meshes depending on the skipper's preference. Average mesh size varied from about 13 to 19 inches stretched (Figure 6a).

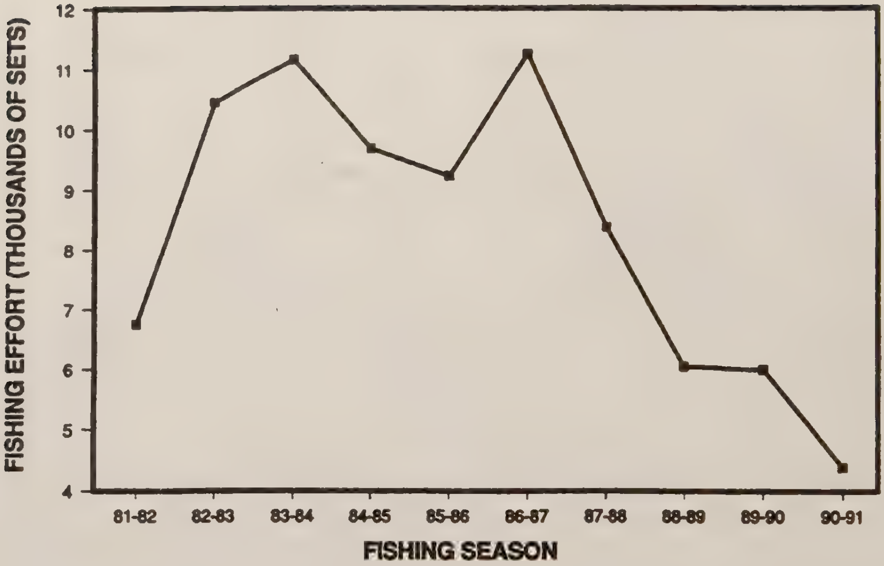

FIGURE 3. Estimated fishing effort in number of sets for California drift gill net vessels by fishing seasons 1981-82 through 1990-91.

Drift gill nets were usually fished with the float line 18 to 26 ft below the surface (Figure 6b) to allow small boats to pass over them. Fishing depth was maintained by tying buoy lines from the float line to bumper-balls at regular intervals of about 60 ft. The bumper-balls floated at the surface to buoy and maintain the net at a desired depth below the surface (Figure 5). The buoy lines were occasionally lengthened to as much as 90 ft when the skipper anticipated targeted fish to be at greater depths. A radar reflector and strobe light on a 6-ft pole was required at the end of the net. The reflectors allowed other boats to detect and avoid the nets and facilitated enforcement of maximum net lengths by patrol boats or airplanes. The bumper-ball floats, also visible on radar, showed the effect of currents and wind on net layout.

The nets were usually deployed or set each evening and usually only one or two people were needed. Deployment started by tossing the radar-reflector buoy overboard. The buoy was attached to the net via several fathoms of line followed by a length of netting sufficient to cause drag. The vessel was driven forward slowly as the net was payed out using the forward momentum of the boat and hydraulic-reel braking to control the speed of deployment. The buoy lines to the bumper-ball floats were snapped to the float line as the net was payed out. To

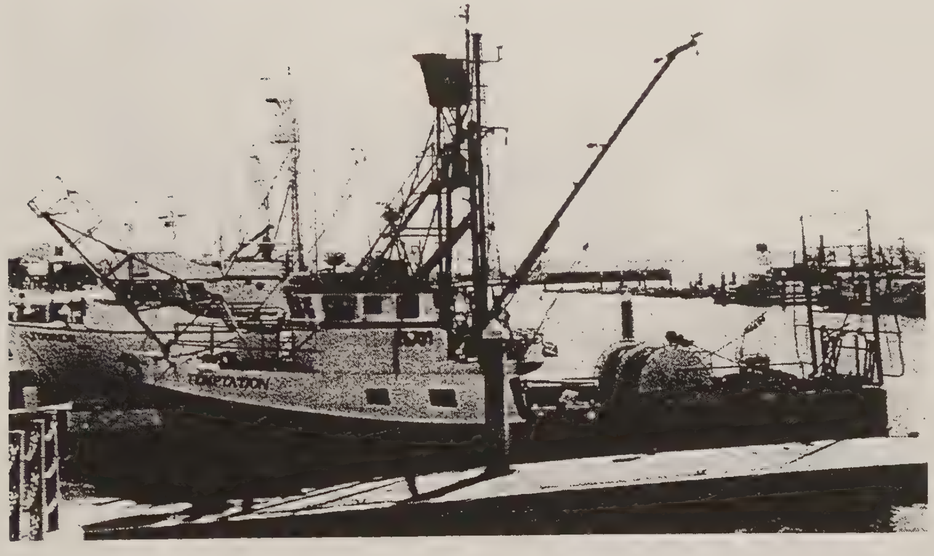

FIGURE 4. California drift gill net vessel with swordfish plank and pulpit at the bow, crow's nest atop the mast, net reel amidships, and net guard raised above the stern.

attract swordfish and increase the catch, many fishermen also attached chemical light-sticks to the net as it was payed out.

The nets were often set perpendicular to currents or across temperature, salinity, or turbidity fronts, because the fish tended to swim along those fronts. Each skipper seemed to choose the area to be fished based on a different set of criteria (e.g. some would not fish during a full moon, others tried to set in water of a particular color, and some tried to set on or near surfacing bait). In general, they tended to fish banks and escarpments which were also productive areas for bait and other fish.

The vessel remained attached to one end of the net while fishing, although sometimes it was detached and moved to the opposite end to change the drift pattern or fishing characteristics. Occasionally, if a net got too close to shore or the vessel drifted back over its net (putting a twist in the net and reducing its fishing capability), the skipper would pull and reset the net.

Nets were fished an average of 9 h. The net was pulled each morning with net pull taking 2 to 4 h. Because the whole net was required to be out of the water by 2 h after sunrise, the time at which a skipper would start the net pull differed depending on expected catch, length of net, duration of net pull, and time of year.

FIGURE 5. Design of typical net in California drift gill net fishery.

The start of a net pull was often between 0100 and 0300 h, ending around sunrise. Net retrieval usually required all hands, each working on a particular task. The net guard was lowered over the stern to keep the net out of the propeller while it was pulled over the stern by the hydraulic net reel. In effect, this caused the boat to be pulled backward until late in the net pull, when the drag of the boat exceeded the drag of the net. Some vessels had rollers on the stern over which the net passed, thus facilitating retrieval and reducing net wear. Most vessels also used vertical guides to direct the net evenly from side to side on the net reel in much the same way as fishing line is wound on a fishing reel. Between sets, the net was stored on the reel, often covered with a tarp.

Most vessels had a secondary control panel (flying bridge), with engine throttle and net reel hydraulic controls, near the stern. As the net was pulled, anything caught in the net was usually seen coming to the surface; the reel was slowed and stopped if the catch was large. The catch was either pulled aboard in the net or, if too large, tied with a line so as not to be lost, and winched aboard.

Once onboard, entangled fish were removed from the net using routine procedures. Shark fins were cut off before removal. With thresher sharks, the tail, which was nearly as long as the body, also was cut off. Swordfish were removed by first

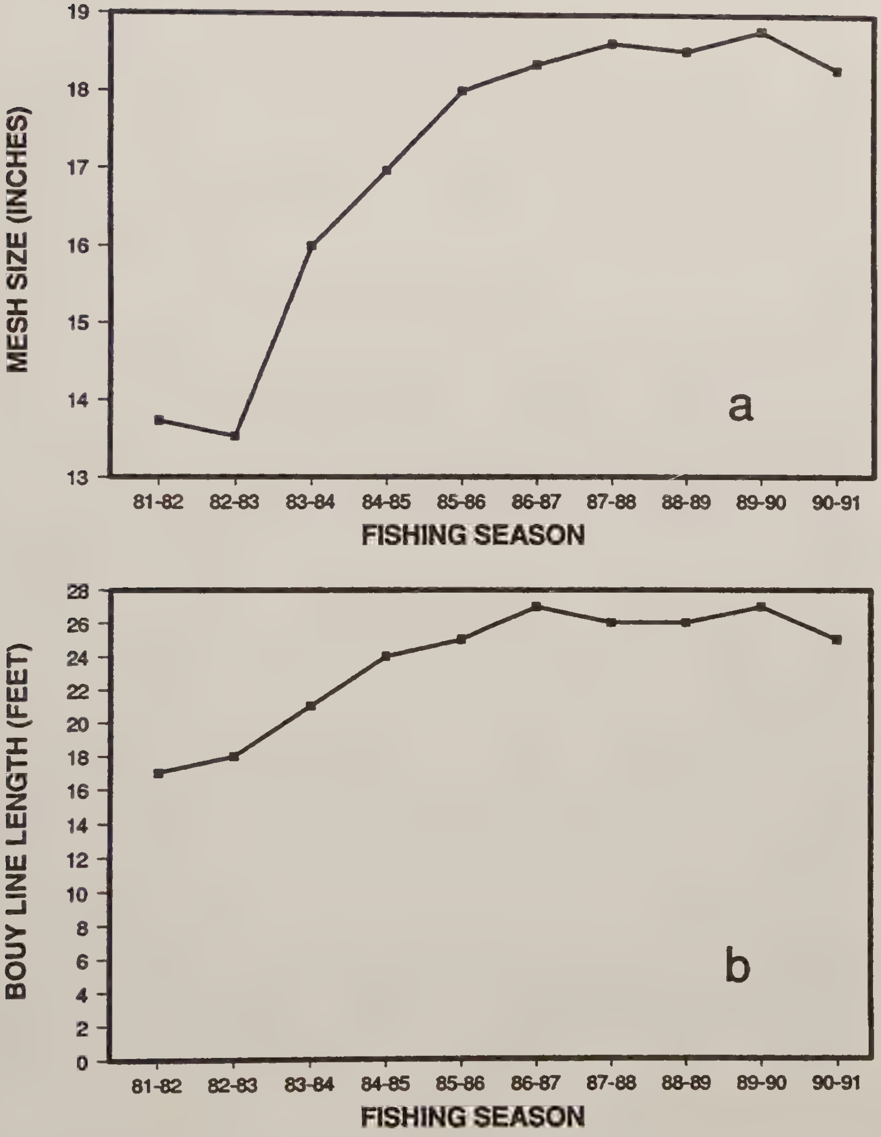

FIGURE 6. Average mesh size in inches (a) and buoy-line length in feet (b) used by California drift gill net vessels during the 1981-82 through 1990-91 fishing seasons.

sawing off the bill or "beak" and then removing the fins. One or more strands of the netting were sometimes cut to remove the entangled catch, but usually only as a last resort and often only with the skipper's permission, since holes in the net reduced fishing capacity and required repair at a later time. Depending on the number of fish caught or the rate at which they were coming aboard, the catch was either cleaned immediately or stacked on deck to be cleaned later. Cleaning of sharks and swordfish included head removal and evisceration. The unwanted parts were discarded at sea and the carcasses washed with sea water. Usually the thin belly meat (belly flaps) was discarded, although the crew would sometimes cook and consume this part. Some skippers kept the shark fins for drying and sale, but most discarded them. If the hold was large enough, shark carcasses were stored separately from swordfish to maintain swordfish quality.

Some fish became entangled early during a set, while others were entangled later or during the net pull. There were no trends in catch locations in the net relative to distance from the fishing vessel or to depth between the cork and lead lines. Except for blue sharks *Prionace glauca*, molas *Mola mola*, and pelagic sting rays *Dasyatis violacea*, most fish were dead when pulled aboard. Blue sharks often swam near or even through the netting as it was retrieved, accounting for many of them being alive when pulled aboard. Since blue sharks are unpredictable and likely to bite, they were usually clubbed immediately, removed from the net, and discarded on the down-current side of the net. The molas were thrown back alive, although sometimes they were kept until completion of the net pull to avoid reentanglement, a frequent occurrence with molas. Pelagic sting rays were removed and immediately tossed overboard. It was common for their tail barb to be hooked in the net, and often just barbs were found indicating they had freed themselves prior to net retrieval.

Marine mammals tended to roll up in the net when caught. Usually a few strands of the net had to be cut to remove them. Most sea lions and seals were dead when retrieved. Those still alive were released at the water line when possible or killed, removed from the net, and discard. If a marine mammal was too large for the hydraulic equipment to pull aboard, it was cut free at the water line.

## Catch

Catches varied by fish species, by season, and among years. Depending on the season and year, one set could yield as many as 15 swordfish, 20 shortfin makos, 20 thresher sharks, and 20 opahs, although many sets caught no marketable fish. Fish buyers often paid a prearranged price for the fish and often had agreements to buy all or a prearranged portion of the catch from a particular vessel. Most of the catch was sold in local markets (Herrick and Hanan 1988). Ex-vessel prices ranged from about $2.00 to $4.00/lb for swordfish, $1.00 to $2.00/lb for shark, and $0.25 to $0.50/lb (round weight) for opah. During the 10-year period covered in this study, mean annual landings were 2 million lb of swordfish, 1 million lb of common thresher, 40,000 lb of bigeye thresher, 3000 lb of pelagic thresher, and 262,000 lb of shortfin mako shark. Average landings over the last 5 years were quite close to the 10-year average, although there were declining trends in the total catch landed for most species (Table 1).

## Effort

Fishing effort used in this study was obtained from skippers' logbooks. Compliance with logbook reporting regulations was estimated to have been greater than 90% (Miller et al. 1983; Beeson and Hanan 1991), therefore total effort estimates based on logs was assumed to be accurate. Other studies have combined logbook information with landing receipt information to improve estimates of effort (Beeson and Hanan 1991); however, to evaluate effort trends we used only the logbook data.

During the 10-year period covered in this study, the annual distribution of effort in the drift gill net fishery shifted geographically from concentration in the nearshore Southern California Bight to more even distribution northward and offshore (Figure 2). Our observations suggest that fishing effort concentrated in the Southern California Bight during spring and shifted northward and offshore as the season progressed. In fall, fishing effort shifted southward to target swordfish. In spite of these general trends, there were also skippers who always fished the Southern California Bight and did not change their area of fishing operations. They preferred not to fish during periods when target species moved to other areas.

In the first 5 years of the study period, total annual effort nearly doubled to a high of 11,000 sets in the 1986-87 fishing season and subsequently declined to a low of 4000 sets in the 1990-91 season (Figure 3). This decline in effort coincides with increasing regulations and laws governing this fishery.

# REGULATIONS AND LAWS PERTINENT TO THE DRIFT GILL NET FISHERY

During a 4-month period (December 1979 through March 1980), swordfish incidentally caught by drift gill net were allowed by the California Fish and Game Commission to be landed and sold. When the Commission denied a request to authorize drift gill net use for catching swordfish, legislation was passed allowing special permits for drift gill net fishing (Hanan 1984; Bedford 1987). The permits were issued to those proving previous experience, significant investment, or competency in the fishery. Permit fees ($150 for shark, $150 for swordfish) were established to fund required research, and the permittee was compelled to be onboard the vessel during fishing operations. Fish buyers were required to pay $0.01/lb privilege tax on thresher sharks and shortfin makos and to report aggregate weight and total number of swordfish received. Recreational fishermen were required to report their catch of striped marlin. The allowable incidental catch of swordfish in the drift gill net fishery was set at 25% of the number of swordfish taken by the commercial harpoon and hook-and-line fisheries in any month. A similar quota of 10% of the recreational catch was set for striped marlin caught incidentally in the drift gill net fishery.

The California Department of Fish and Game (CDFG) was directed by the Legislature to study the drift gill net shark fishery, determine the effects of the fishery on swordfish and striped marlin, set up an observer program to observe the fishing operations on vessels fishing under drift gill net and harpoon permits, and report its findings. A mandatory daily logbook system was established. Drift gill net mesh sizes were set at 8 inches or larger, twine size at #18 or larger, and net length at 6000 ft or less. Additionally, the nets could be fished only between 2 h before sunset and 2 h after sunrise.

Because regulations for the drift gill net fishery were to expire in 1982 and there was legislative interest in continuing to regulate the fishery, new legislation was enacted which allowed direct targeting of commercial fishing on swordfish during a portion of the year. Commercial landings of swordfish were not tied to the sport or commercial catch of marlin or shark as had previously been required. This legislation also established the drift gill net fishery as a limited entry fishery with a maximum of 150 permits. Because the actual number of permits exceeded 150 at that time, new entrants were not allowed into the fishery until the actual number of permits issued dropped below 150. The bill increased the minimum stretched mesh size requirement to 14 inches, required the permittee to specify the fishing vessel on which the permit would be used, and specified that each net would have a radar reflector at least 10 inches in diameter on a 6-ft pole at the net end opposite the fishing vessel.

To control the incidental catch of seals and sea lions, the same legislation established time and area closures for the early summer (1 May through 31 July) around the Channel Islands. The bill also established time and area closures between the Channel Islands and the mainland during periods of expected high use by recreational or harpoon fishermen and closed the drift gill net fishery for sharks during 1 February through 30 April. It specified that during 1 May through 15 September, incidental landings of swordfish must not exceed landings of thresher shark and shortfin mako for any permittee during any calendar month, but it allowed swordfish to be landed from 16 September through 31 January without any shark poundage landing requirement. It gave the CDFG power to evaluate and close the shark and swordfish fisheries if landings of either exceeded 1.5 million lb during any 12-month period.

In 1984, an additional 35 permits were established for taking swordfish north of Point Arguello. This legislation was passed to allow entry into the drift gill net fishery to fishermen who may have missed the earlier opportunity as the fishery developed off southern California and moved northward to central and northern California.

Legislation passed in 1985 eliminated the equal shark-swordfish landing requirement and established new time and area closures intended to reduce the bycatch of marine mammals. The closures prohibited drift gill nets within 25 nautical miles of the mainland coast from 15 December through 31 January and within 75 miles of the mainland coast from 1 June through 14 August. It set the drift gill net season to 15 August through 31 January. It established a fee of $100 to transfer the permit to a boat other than the one specified on the application. A "shark drift gill net" was defined as "a drift gill net of 14 inches or greater mesh size." The legislation allowed for a maximum of 250 fm of spare or replacement netting to be aboard the fishing vessels at any time.

In 1986, the drift gill net fishery was eliminated within 12 miles of the coast north of Point Arguello and in certain areas in the Gulf of the Farallones near the mouth of San Francisco Bay. The thresher shark fishing season was reduced to 30 days in May.

More time and area closures were added in 1987 within the Southern California Bight and net length restrictions were clarified.

In 1988, legislation required that pelvic fins be left intact on thresher sharks until after landing to enable sex determination during market sampling by the CDFG. Also swordfish could be sold only to licensed fish buyers or dealers.

The U.S. Congress passed legislation in 1988 amending the Marine Mammal Protection Act of 1972 (MMPA). The amendments required vessels owners in the drift gill net fishery, which was considered likely to have marine mammal interactions, to obtain and display Federal MMPA exemption permits, report marine mammal kills, and allow Federal observers to board and observe fishing operations.

Legislation enacted in 1989 prohibited drift gill net fishing within 75 nautical miles of the mainland from 1 May through 14 July and continued the previously enacted prohibition from 1 February through 30 April; thus, it virtually eliminated the directed thresher shark fishery in California. It also directed the CDFG to revoke permits for specified findings and allowed permit transfers between fishermen for a fee of $1000. It eliminated the requirement for drift gill net permits for taking sharks north of Point Arguello.

Also in 1989, the states of California, Oregon, and Washington enacted a tristate interjurisdictional fishery monitoring plan for thresher sharks (PSMFC 1990).

During 1990, the drift gill net permit fee was temporarily increased to $330 ($250 for a partial year), a one-time between-boat permit transfer fee of $130 was continued, and a $1500 fee to transfer permits between fishermen was established.

## BYCATCH

Observer programs were mandated for the developing drift gill net fishery in 1980 and observation begun in October of that year; thus, detailed data were gathered on incidental catches during the early years of this fishery. There were no systematic observations during the 1986-87 through 1989-90 fishing seasons, after which the National Marine Fisheries Service (NMFS) established an observer program as mandated by the MMPA. Data were recorded by observers onboard or nearby the drift gill net vessels during observed net pulls. Observers recorded detailed fishing information including number of each species in the catch.

During the first 6 years of the fishery, the CDFG had two observer programs. The first observed 262 net pulls during the 1980-81, 1981-82, and 1982-83 fishing seasons. These observations were made by observers who boarded drift gill net vessels prior to leaving the fishing port and stayed aboard until the vessel returned to port. The second program observed 181 net pulls during the 1983-84, 1984-85, and 1985-86 fishing seasons. These observations were made by observers transferred to the drift gill net vessels from a CDFG vessel at the fishing grounds just prior to the net pull and transferred back to the CDFG vessel after completion of the net pull. This method of obtaining observations allowed more random selection of drift gill net vessels than the previous program, since any vessel on the fishing grounds could be boarded and observed during a net pull without regard for living space—a major consideration in selecting vessels to observe during the first observation program.

The NMFS established a mandatory drift gill net observer program during the 1990-91 fishing season and observed 195 net pulls using a sampling scheme similar to the first CDFG program. The program differed by requiring vessels to take observers on a preset proportion of the fishing trips (Lennert et al. 1991).

Observers recorded bycatch by taxon for fish, mammals, and turtles (Table 2). The potential catch of striped marlin was of particular concern to all involved in this fishery, since striped marlin were designated a sport fish in California and were not to be sold even if caught incidentally in commercial fisheries. Drift gill net fishermen were required to notify the CDFG when marlin were caught and to surrender them to the CDFG upon docking. The bycatch of striped marlin was closely monitored while the CDFG observer program was in existence. During that period, the striped marlin bycatch (Table 3) was not considered large enough to warrant additional closures or further restrictions of the fishery (Bedford 1985).

Pinnipeds and turtles, as well as small and large cetaceans, were observed caught in the drift gill net fishery (Table 3), although large cetaceans tended to break through the nets or to break free after entangling. Observations of marine mammals caught incidentally to the fishing operations (Diamond et al. 1986, 1987) were used with estimates of fishing effort to calculate total marine mammal mortalities by time and area in the fishery (Hanan et al. 1988; Herrick and Hanan 1988; Hanan and Diamond 1989; Lennert et al. 1991; Perkins et al. 1991, 1992). There were no major changes in the rates of entanglement during the period examined except for a decrease in the catch rate of pinnipeds near the Channel Islands after the implementation of time and area closures. Part of the rationale for a fishing closure within 25 miles of shore was to protect gray whales *Eschrichtius robustus*, although there were no observations of gray whales killed in the drift gill net fishery and apparently no significant effect on the population (Heyning and Lewis 1990). Heyning and Lewis (1990) also state that the entanglement of balaenopterid whales may be substantial in this fishery. Miller et al. (1983) estimated, based on dock-side interviews of fishermen, that three gray whales and one large baleen whale were killed in this fishery in 1980.

Two species of sea turtles, Ridley's *Lepidochelys olivacea* and loggerhead *Caretta*, were observed caught in the drift gill net fishery (Diamond et al. 1986, 1987). All turtles caught appeared to be dead when removed from the nets.

As mentioned above, some of the incidental catch (e.g. swordfish and opahs) became important and were even targeted as the fishery evolved. Basically, the fishermen kept what could be sold and released or discarded that which could not be sold (e.g. blue sharks, molas, and marine mammals).

[a] *There were 262 net pulls observed during the period October 1980 to April 1983 when the fishery was allowed year-round. Bycatch-rate data are presented for only the May through January period to allow comparison to subsequent years when the fishery was closed February through April. There was an additional closure within 75 miles of shore 1 May through 14 July 1990, but all data for the 1990-91 season are presented.*

[b] *This represents one animal, which was released alive.*

From a political viewpoint, the important species in the bycatch were gray whale, striped marlin, minke whale *Balaenoptera acutorostrata*, California sea lion, common dolphin *Delphinus delphinus*, and blue shark; from an economic viewpoint, swordfish, albacore, and opah. Species of special interest or novelty included megamouth shark *Megachasma pelagios*, basking shark *Cetorhinus maximus*, and white shark *Carcharodon carcharias*.

## STATUS OF BIOLOGICAL KNOWLEDGE

### Swordfish

Swordfish have a cosmopolitan distribution in tropical, subtropical, and temperate waters of the Pacific Ocean between lat. 50°N and 45°S and usually in water temperatures greater than 13°C (Nakamura 1985). Areas of highest apparent abundance (based on hook rates from worldwide longline fisheries) occur in waters off Australia, Mexico, Peru, Japan, and in the North Pacific Transition Zone (Sakagawa and Bell 1980). Swordfish larvae are found throughout the tropical central and western Pacific and are often associated with the 24°C surface isotherm (Nishikawa and Ueyanagi 1974).

Swordfish are both epipelagic and mesopelagic and have been reported to depths of at least 550 m. Sonic tracking experiments off southern Baja California, Mexico indicate that swordfish move from inshore areas during the day seaward to deeper areas at dusk and return to inshore areas at sunrise. Larger swordfish tend to spend more time farther offshore (Carey and Robison 1981; Carey 1990). The number of swordfish tagged in the Pacific is very low and returns have yet to confirm trans-Pacific movements. Catch records from Japanese longliners suggest a movement from the tip of Baja California in the spring northward in the summer and fall to at least the waters off California (Kume and Joseph 1969). Catch records from the California drift gill net fishery show swordfish passing through the fishery from August through January (Sakagawa 1989).

Data on length-weight relations for swordfish in the Pacific are very limited. Skillman and Yong (1974) described the relation as

$$W = 2.3296 \times 10^{-7} L^{3.5305}$$

where W = round weight (kg) and L = length from tip of upper bill to fork (cm). However, the relation is based on a sample of only seven fish between 150 and 325 cm. More length-weight data from larger samples and greater length ranges are available for swordfish in the Atlantic Ocean (Palko et al. 1981).

Most swordfish are landed dressed; a conversion factor from dressed weight to round weight was established by California Fish and Game Commission for landing-tax purposes. The regulation specifies that, for taxing, round weight be 145% of the landed weight (Calif. Code of Reg., Title 14, section 187).

There is good evidence that male and female swordfish grow at different rates with females attaining the larger sizes (Kume and Joseph 1969). While male swordfish seldom exceed 140 kg, females may grow to 500 kg in the South Pacific. Swordfish in the western Pacific grow approximately 25 to 30 cm/year, whereas swordfish in the eastern Pacific grow approximately 38 cm/year. Approximate ages at length are as follows (Yabe et al. 1959):

| Fork length (FL) range (cm) | Age Months | Age Years |
|---|---|---|
| 38- 68 | 6-17 | 1 |
| 68- 98 | 18-29 | 2 |
| 98-128 | 30-41 | 3 |
| 128-158 | 42-53 | 4 |
| 158-189 | 54-65 | 5 |

Swordfish spawn throughout the year in warm equatorial waters, usually in close proximity to the 24°C surface isotherm (Nishikawa and Ueyanagi 1974). However, fish in spawning condition are caught more frequently during March through July in the northern latitudes and during January in the southern latitudes (Kume and Joseph 1969). There is some evidence of seasonal spawning 1 to 2 months earlier in the southwestern Pacific than around Hawaii (Matsumoto and Kazama 1974). First spawning occurs at 5 or 6 years. Fecundity is estimated at 2 to 5 million eggs per spawning in the western Pacific (Nakamura 1985).

Larval swordfish, 9.0 to 14.0 mm total length (TL), feed on organisms such as mysids and amphipods, and start feeding on fish at about 21 cm (Yabe et al. 1959). Juveniles and larger swordfish are opportunistic feeders concentrating on areas of high food abundance. They feed on local species of squid, fish, and pelagic crustaceans during the night (Scott and Tibbo 1968), and various bottom species while inhabiting deeper waters during the day (Nakamura 1985). The Southern California Bight provides swordfish ample prey during the summer and fall months around offshore banks and submarine escarpments.

There are no estimates of natural (*M*) or fishing (*F*) mortality rates for swordfish in the Pacific Ocean. Because of their longevity, *M* is thought to be low compared to other billfishes. Estimates of *M* for northwestern Atlantic swordfish range from 0.21 to 0.43 and estimates of total mortality rates range from 0.12 to 0.65 for the harpoon fishery and 0.16 to 0.59 for the longline fishery (Beardsley 1978).

Currently, there are two stock-structure hypotheses for Pacific swordfish (Sakagawa and Bell 1980). The first hypothesis suggests a single Pacific-wide stock in a contiguous distribution with zones of high catches, high abundance, and the assumption that the population is sufficiently mobile within its range to prevent local depletion. The second hypothesis emphasizes three stocks in areas of high abundance made contiguous over a broad area of low abundance. In both cases, stock assessments conclude that Pacific swordfish populations are not overfished and that the resource is healthy (Bartoo and Coan 1989) and being fished at levels much lower than in the mid-1960s.

## Thresher Sharks

Three species of thresher sharks are taken in California's drift gill net fishery: common thresher, bigeye thresher, and pelagic thresher. Although all three are closely related and share many common traits, they are caught at vastly different rates in this fishery.

### *Common Thresher*

Common threshers are distributed throughout all tropical and temperate oceans. They are both coastal and oceanic but have a greater apparent abundance within 40 miles of shore (Strasburg 1958). They are strong swimmers, although transoceanic migrations are undocumented in the Pacific. In the eastern North Pacific they are abundant over the continental and insular shelves (Compagno 1984a), distributed seasonally from Baja California to Vancouver Island, British Columbia.

Common threshers move northward from Baja California into southern California following the warmwater isotherms in early spring. Large mature common threshers continue northward to at least Vancouver Island in late summer and fall, where the sex ratio can be five males per female (Stick and Hreha 1988, 1989). Presumably there is a southward movement in winter. Juveniles tend to remain in shallow, nearshore areas especially within the Southern California Bight, which may be an important nursery area (Bedford 1992). Immature fish are seldom found north of Cape Mendocino, California (Holts and Bedford 1989).

The caudal fin or tail of thresher sharks represents about 50% of total body length. Minimum size at birth was estimated at 139 cm TL, while maximum total length, based on a sample of 143 common threshers taken off California, was estimated at 636 cm for females and 493 cm for males (Cailliet and Bedford 1983). Maximum age was also estimated to be as high as 45 to 50 years (Cailliet et al. 1983).

The relation between alternate length (AL, distance from origin of first dorsal fin to origin of second dorsal fin) and dressed weight was determined for 110 common threshers (combined sexes) sampled at Washington and Oregon ports (Stick and Hreha 1988). That relation was

$$W = 0.001305(AL)^{2.750031}$$

were W = dressed weight (lb) and AL = alternate length (cm). There are no data relating dressed to round weight for common threshers. The California Fish and Game Commission established regulations for determining landing taxes which specify a 170% factor of the landed weight to be the round weight for taxing purposes.

Reproduction in common threshers is ovoviviparous. After absorption of the yolk sac, developing fetuses obtain nourishment by eating eggs still developing in the uterus (Bigelow and Schroeder 1948; Otake and Mizue 1981). Females mature at 315 cm TL in the Pacific (Strasburg 1958) and males reach maturity at about 333 cm TL (Cailliet and Bedford 1983). Mating occurs in summer. Gestation lasts 9 months and female common threshers give birth each spring (March to June) to an average of four fully developed pups (Bedford 1985).

Thresher sharks use their tail to thrash and stun their prey. In the eastern North Pacific, their diet consists of small pelagic species including anchovies, herring, mackerel, sardines, and squid (Hart 1973; Stick and Hreha 1989).

Due to their long life and the advanced stage and condition of newborn pups, natural mortality is presumed low. There has been one attempt at estimating fishing mortality for the eastern Pacific common thresher. Hanan (1984) suggested sustainable mortality rates for a closed fishery, although preliminary, were very low ($F = 0.007$ to 0.049), implying that only a small portion of the stock could be removed annually without compromising the stock.

Separate oceanic stocks may exist; differences have been observed in numbers of offspring and size at maturity in the Indian Ocean (Gubanov 1972) and in the North Pacific (Strasburg 1958; Cailliet and Bedford 1983). Fishery data suggest that the common thresher resource off California consists of a single, coast-wide stock. This stock appears to have a seasonal north-south movement pattern. Numerous thresher sharks taken off the California coast have carried hooks from the Japanese billfish and tuna longline fishery indicating long-distance movement from southern or offshore areas (Bedford 1985). However, the declining catch and smaller size of individuals in the catch indicate immigration has not kept pace with the harvest rates predicted by Hanan (1984). A preliminary population assessment for the 1980-84 period, using catch per unit effort and cohort analysis, indicated that the local stock could not sustain the level of catch evaluated in that 4-year period of study (Berkson 1985). More complete or rigorous stock assessments have not been conducted. During the period and area of this study, fishery data showed that catches of common thresher decreased and the average size remained small in spite of the numerous regulations restricting fishing effort (Cailliet et al. in press).

## *Pelagic Thresher*

Pelagic threshers are found in tropical Pacific and Indian Ocean waters. They are oceanic and epipelagic and occasionally found near inshore areas. Little is known concerning their movements off the coasts of California and Mexico.

They are smaller than other thresher sharks and grow from 96 cm at birth to 330 cm maximum length (Compagno 1984a). Reproduction is ovoviviparous with two pups per litter. Size at maturity is not well documented but is between 264 and 282 cm TL (Otake and Mizue 1981; Compagno 1984a).

There is no information on mortality rates or stock status in the Pacific. Evidence from the longline fishery suggests a population center off central Baja California which shifts northward during strong El Niño events.

## *Bigeye Thresher*

Bigeye threshers, like common threshers, are oceanic and coastal in tropical, sub-tropical, and warmer temperate seas. They are epipelagic and have been reported to depths of at least 500 m (Compagno 1984a). In the eastern North Pacific they are found on the high seas, over continental and insular shelves, and occasionally in shallow inshore areas. The first report of this species from southern California waters was of a 1963 occurrence of a bigeye thresher caught in a set gill net (Fitch and Craig 1964).

Maximum reported size is 461 cm TL for females and 378 cm TL for males. Size at birth is between 64 and 106 cm TL (Gruber and Compagno 1981). The length-weight relation reported for 16 Atlantic bigeye threshers by Stillwell and Casey (1976) is

$$\text{Log } Y \text{ (WT)} = 11.1204 + 2.99269 \text{ Log } X \text{ (FL)}$$

where WT = weight (kg) and FL = fork length (cm).

Reproduction is ovoviviparous as in other thresher sharks. Males mature at about 300 cm TL (3 to 4 years) while females become sexually mature at about 350 cm TL (5 to 6 years old; Gruber and Compagno 1981).

Bigeye threshers have specialized eyes adapted to low light levels. Their eyes can roll up into upward-directed sockets allowing them to feed on prey species silhouetted above. Their prey consists of small pelagic fish, squid, and crustaceans (Stillwell and Casey 1976; Gruber and Compagno 1981).

Although fished throughout its range, very little is known about mortality rates, stock structure, or stock status. The species is widely, though sparsely, distributed and may commonly inhabit deep water (Gruber and Compagno 1981).

## Shortfin Mako

Shortfin makos are found in all tropical and warmer temperate oceans and in both coastal and open-ocean habitats. In the extreme northern and southern portions of their range, they follow warm water masses poleward in summers. They are highly migratory and considered one of the fastest and most active ocean predators (Compagno 1984a). General movement patterns or centers of abundance in the eastern North Pacific are not well known (Strasburg 1958). Juveniles are generally caught more frequently in the waters off southern California in the summer months and seldom caught north of the Mendocino Escarpment. Juveniles are near-surface swimmers and rarely descend below the thermocline (Holts and Bedford in press). Adults are occasionally caught around the Channel Islands and outer banks of the Southern California Bight in late summer.

Maximum total length reported is 390 cm for females and 280 cm for males. The largest shortfin mako reported off California was 351 cm and weighed 468 kg (Applegate 1976). Cailliet et al. (1983) estimated von Bertalanffy asymptotic growth from 44 southern California shortfin makos (combined sexes) at $L_\infty =$ 321 cm TL, with an estimated life span of 45 years. Pratt and Casey (1983), assuming two vertebral growth bands per year, determined asymptotic growth from 109 Atlantic shortfin makos at $L_\infty =$ 345 cm FL for females and 302 cm FL for males. Strasburg (1958) described the length-weight relation as

$$\log \mathrm{WT\ (lb)} = -4.608 + 2.925 \times \mathrm{TL\ (cm)}$$

for central Pacific shortfin makos, and Stevens (1983) reported

$$\mathrm{WT\ (kg)} = 4.582 \times 10^{-6}\ \mathrm{TL}^{3.10}\ \mathrm{(cm)}$$

from 80 shortfin makos taken off New South Wales.

Reproduction is ovoviviparous with 4 to 16 pups per litter. Gestation is about 1 year with parturition occurring in late spring followed by mating in the summer months. Females mature at 280 cm TL (7 to 8 years) and males mature at 195 cm TL. Mean size at birth is 70 cm TL (Stevens 1983).

Shortfin makos are active feeders on a variety of epipelagic species (Stillwell and Kohler 1982). Off California these include mackerel, bonito, anchovy, tuna, other sharks, and squid. They are even known to kill and eat swordfish (Bigelow and Schroeder 1948).

There are no estimates of natural or fishing mortality rates for the shortfin mako. Stock structure and abundance of shortfin makos in the eastern Pacific are poorly understood. Length-frequency and catch data from the drift gill net fishery suggest that southern California waters are part of an important nursery area for shortfin makos in the eastern Pacific.

## Blue Shark

Blue sharks are circumglobal in all tropical and temperate waters. In the North Pacific, seasonal migrations occur between lat. 20° and 50°N. They are epipelagic and generally considered abundant in the offshore and coastal waters of the western United States and Mexico (Compagno 1984b). The northward movement extends into the Gulf of Alaska as waters warm during summer months. Movement southward occurs during winter months (Strasburg 1958). In coastal areas, mature females tend to start their northward journey in early spring as warm water moves northward, while juveniles of both sexes follow closely. Large males start later and tend to stay farther offshore (Bedford 1985). Juveniles and subadults are abundant within the Southern California Bight and in Monterey Bay from May to October (Sciarrotta and Nelson 1977; Tricas 1979).

Cailliet and Bedford (1983) determined asymptotic growth ($L_\infty$) from 130 southern California blue sharks at 242 cm TL for females and 295 cm TL for males. Length-weight relations for Pacific blue shark were described by Nakano et al. (1985) as

$$WT = 3.838 \times 10^{-6} \ L^{3.174} \text{ for males}$$

$$WT = 2.328 \times 10^{-6} \ L^{3.294} \text{ for females}$$

where WT = weight (kg) and L = precaudal length (cm). Strasburg (1958) reported

$$\log WT = -5.396 + 3.13439(\log TL) \text{ for combined sexes}$$

where WT = weight (lb) and TL = total length (cm).

Blue sharks are viviparous, thus developing embryos are initially nourished from a yolk sac. Once the yolk sac is exhausted, developing young obtain nourishment and oxygen from the maternal blood stream through a placenta. Females mature at 140 to 160 cm FL (5 to 6 years) and males mature a year earlier between 130 and 160 cm FL (Nakano 1991). Maximum age is estimated to be at least 20 years (Cailliet and Bedford 1983; Nakano 1991). Gestation is 9 to 12 months. Brood size varies considerably depending on the female's size and condition, with over 100 young in a single brood reported, although 20 to 40 young are more typical (Strasburg 1958). Nakano (1991) examined 669 pregnant females from the North Pacific and found a mean litter size of 25.6 pups with an overall sex ratio of 1:1. Off California, parturition occurs in early spring and mating occurs during late spring to early winter. The Southern California Bight is a major pupping area and generally considered a nursery area for immature blue sharks. They are often seen on calm days moving slowly with dorsal fin and tail lobe protruding from the water.

In the coastal waters off California, blue sharks feed on anchovy, mackerel, hake, dogfish, squid, and pelagic crustaceans (Tricas 1979; Harvey 1989). Juveniles may make shoreward movements at night to feed in shallow water especially in the Southern California Bight, where numerous islands and submerged banks attract ample prey (Sciarrotta and Nelson 1977).

The size of the blue shark stock subject to the drift gill net fishery is unknown. There are no local or Pacific-wide estimates of stocks or abundance. Local availability undergoes major seasonal fluctuations with more juveniles (1 to 3 years old) caught in the coastal waters from early spring to early winter. Mature adults are uncommon in coastal waters. Local abundance probably depends on recruitment from coastal Mexican and offshore areas. A blue shark tagged off southern California was recovered near Midway Island in the central Pacific (J.S. Sunada, CDFG, pers. comm.), suggesting that it is a cosmopolitan species and that the local stock is not a closed population.

Fishery-dependent and -independent data needed for determining abundance, mortality, and distribution are inadequate. Blue sharks caught incidentally are usually discarded because the meat is considered unsuitable for human consumption; thus this catch often goes undocumented and little biological data are gathered.

### Opah

Opahs are found in all tropical and temperate oceans. In the eastern North Pacific they are caught in the drift gill net fishery for swordfish, by trollers from the Gulf of California to the Gulf of Alaska (Hart 1973), and as incidental catches in other fisheries operating off southern California. They are rarely caught in large numbers and are thought to be widely but sparsely distributed (Allen 1992). General movement patterns are unknown, although opahs occur in the waters off California at all times of the year to depths of 365 m (Harald 1939). These fish may reach 180 cm and exceed 225 to 275 kg in the Atlantic. The largest reported off California was 73 kg (Harald 1939).

Opah feed on crustaceans, cephalopods, and small boney fishes (Allen 1992). There is little information on growth, reproduction, stock size, or status of the opah stock. They are apparently more abundant off California following El Niño years. Because opah is not a target species in any fishery, current landings probably have little impact on the population as a whole (Allen 1992).

### Tuna

The California drift gill net fishery occasionally catches albacore, skipjack, bigeye, and yellowfin tunas. The status of biological knowledge, stock status, and summaries of directed fisheries for those species can be found in Bartoo (1987), Bayliff (1992), Laurs and Dotson (1992), and Wild (1992).

## CATCH ANALYSIS

### Landings

Commercial fish buyers have been required to complete a landing receipt (Figure 7) for each landing purchased in California since the early 1900s. The buyer recorded species landed, quantity landed (pounds), price, and fishing gear used (Bureau of Marine Fisheries 1952). Other data such as area fished could have been reported on the landing receipts but often these sections were left blank.

While the instructions for the landing receipts asked buyers to report gill net landings by type of gill net (drift or set), the receipts have an entry only for generic gill net (coded as entangling net in the data base). Because of this ambiguity on the receipt, fish buyers at times neglected to identify the type of gill net used. Also, swordfish, thresher sharks, and shortfin makos, species typically caught by drift gill net, were sometimes reported taken by gear such as trawls, trammel nets, and encircling net—gear that does not ordinarily catch these species. FISHERMAN COPY

FIGURE 7. Current landing receipt used by commercial buyers of fish landed by the California drift gill net fishery.

cause of these problems associated with reported gear types, criteria were developed to estimate actual landings of the drift gill net fishery.

Landing receipts were separated into three categories: 1) landings with gear reported as drift gill net, 2) landings by vessels with drift gill net-permitted skippers but with gear reported as other than drift gill net, and 3) landings with gear reported as entangling net, trawl, trammel net, encircling net, or set gill net. All landings in category 1 were assumed correct and summed directly as drift gill net landings. (This included the landings for a relatively small number of vessels using drift gill nets and targeting species such as California barracuda, white seabass, and yellowtail *Seriola lalandi*. These vessels fish nearshore waters and use nets with 6-inch or smaller mesh. Their landings are included in Tables 1 and 2.)

Criteria for identifying and separating drift gill net landings from categories 2 and 3 were based on category 1 landings for the 1981-82 and 1982-83 seasons, the period with the fewest reports of catch by unspecified net type (no net type reported in the landing receipt gear code section). Landings for this period were summarized to determine the relative proportions of fish species for both drift and set gill nets. Typically, drift gill net landings had catch proportions of swordfish greater than 20%, thresher shark greater than 30%, and shortfin mako greater than 18%; whereas landings from set gill nets had catch proportions of swordfish less than 6%, thresher shark less than 8%, and shortfin mako less than 2%. Relatively large percentages of Pacific herring *Clupea pallasi* (greater than 70%) were identified as set gill nets. Also noted in set net landings were angel shark, rays, and skates; these nearshore species were rarely reported in drift gill net landings.

Based on the above findings, category 2 and 3 landings were considered drift gill net landings if no Pacific herring was landed and if landings receipts reported gear as entangling nets, trammel nets, trawls, encircling nets, or set gill nets and the landing contained more than 20% swordfish, 30% thresher shark, or 18% shortfin mako. Landings were not included in the drift gill net summaries if angel sharks, rays, skates, or California sheephead *Semicossyphus pulcher* were reported.

Landings in category 2 were screened with additional criteria if the reported gear was "unknown." These landings were considered drift gill net landings if 1) swordfish was greater than 20% and thresher shark greater than 30% of the fish landed, or 2) swordfish landed was greater than 20% and shortfin mako was greater than 18%, or 3) thresher shark was greater than 30% and shortfin mako was greater than 18%. These criteria were developed to insure that "gear unknown" landings reported as 100% swordfish would not be included as gill net landings, but more appropriately as harpoon landings.

Data summarized with the above criteria show that the number of drift gill net vessel landings increased to a high of 3500 in the 1983-84 season and decreased steadily to a low of 1500 in the 1990-91 season (Figure 8a). The number of drift gill net vessels peaked in 1985-86 at 309 and decreased to less than 200 in the 1990-91 season (Figure 8b). The number of vessels shown in Figure 8b are at times higher than the annual 250-vessel permit limit. This was caused by the criteria used to estimate drift gill net fishery landings, where some landings with

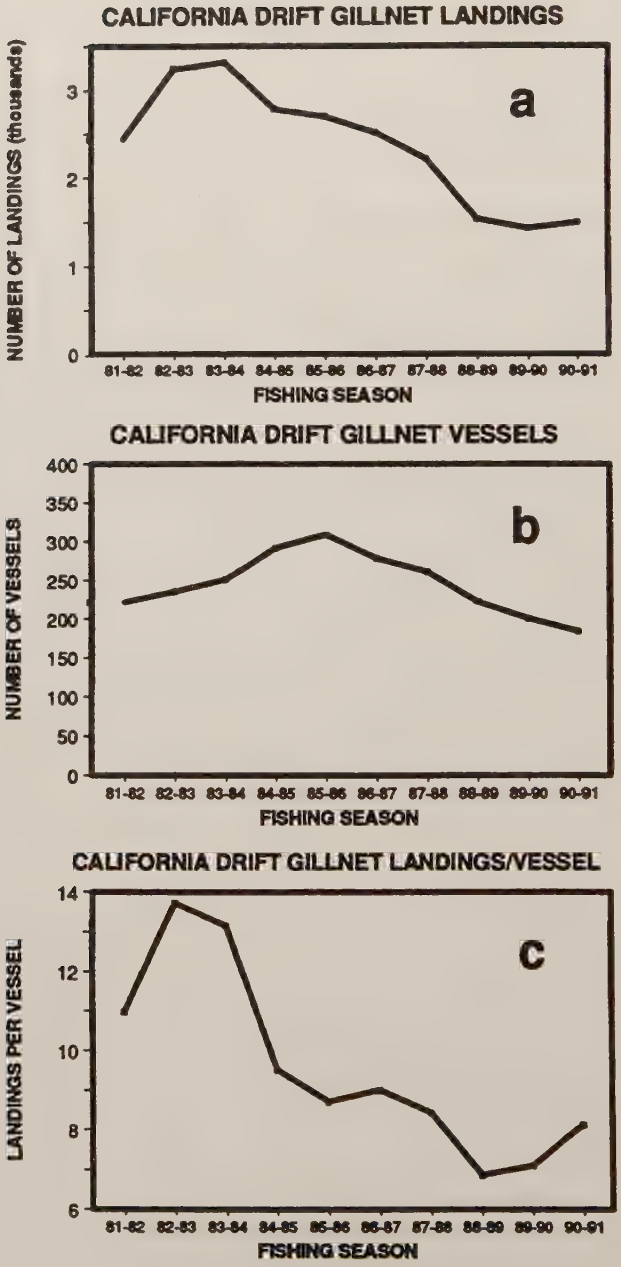

FIGURE 8. Number of landings (a), vessels (b), and landings per vessel (c) for the California drift gill net fishery, 1981-82 through 1990-91.

gear identified as drift gill net were made by a nonpermitted vessel. Landings per vessel decreased sharply from a high of 13 in the 1982-83 season to lows of seven and eight in the 1988-89 to 1990-91 seasons (Figure 8c).

The principle species landed by the drift gill net fishery were swordfish, common thresher, and shortfin mako (Table 1). Common thresher dominated the catch in the 1981-82 (60%) and 1982-83 (48%) fishing seasons, but swordfish dominated during the 1983-84 to 1990-91 (53% to 68%) fishing seasons (Figure 9). Swordfish landings increased from a low of 700,000 lb in the 1981-82 season to a high of 3.4 million lb in the 1984-85 season and then declined to 1.5 million lb in the 1990-91 season. Common thresher landings decreased steadily from a high of 2.2 million lb in the 1981-82 season to a relatively constant level of 400,000 to 500,000 lb during the 1986-87 to 1990-91 seasons. Landings of shortfin mako peaked in the 1982-83 season at 500,000 lb, but have remained relatively stable between 200,000 and 300,000 lb since then.

Other species were also landed in the drift gill net fishery, although in lesser quantities (Table 1). The largest quantity in this group was tuna, dominated by albacore which peaked at over 200,000 lb in the 1985-86 season and dwindled to 23,000 lb in the 1990-91 season. Shark landings other than thresher and shortfin mako were dominated by the "unspecified shark" category during the early seasons and by soupfin shark during the later seasons. The recorded high landings of over 200,000 lb of "unspecified shark" in the 1981-82 season may include a high rate of accidental or intentional misidentification of illegally caught and landed swordfish. Opah dominated catches of other fish species and reached a high of 260,000 lb in the 1984-85 season.

## Logbooks

Logbooks have been collected from skippers of California drift gill net vessels under a mandatory logbook system implemented in 1980 (Huppert and Odemar 1986). Data collected from the logbooks include catches (number of fish) by species, date, mesh size, length of net, hours soaked, set number, geographical position of set, and other information such as the drift gill net permit number and vessel registration number (Figure 10).

Geographical positions entered on logbooks were CDFG block numbers (usually a 10-min square). We converted these block numbers to latitude and longitude for plotting. Some catch locations were either a series of block numbers or blocks larger than a 10-min square. For those cases, a latitude and longitude for a quadrangle encompassing all of the catch locations was chosen (e.g. 1°, 5°, 5° x 10°, or larger quadrangle).

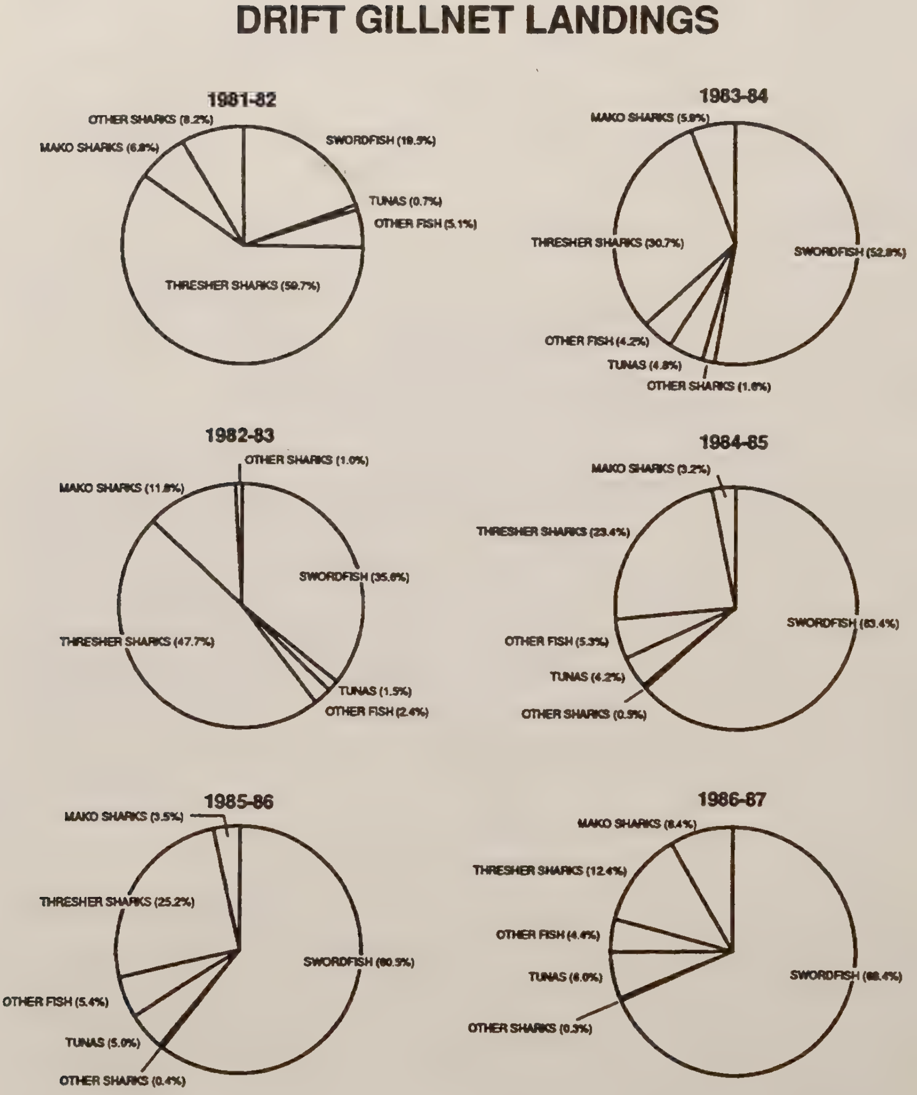

FIGURE 9a. Species composition of California drift gill net landings for the 1981-82 through 1986-87 fishing seasons.

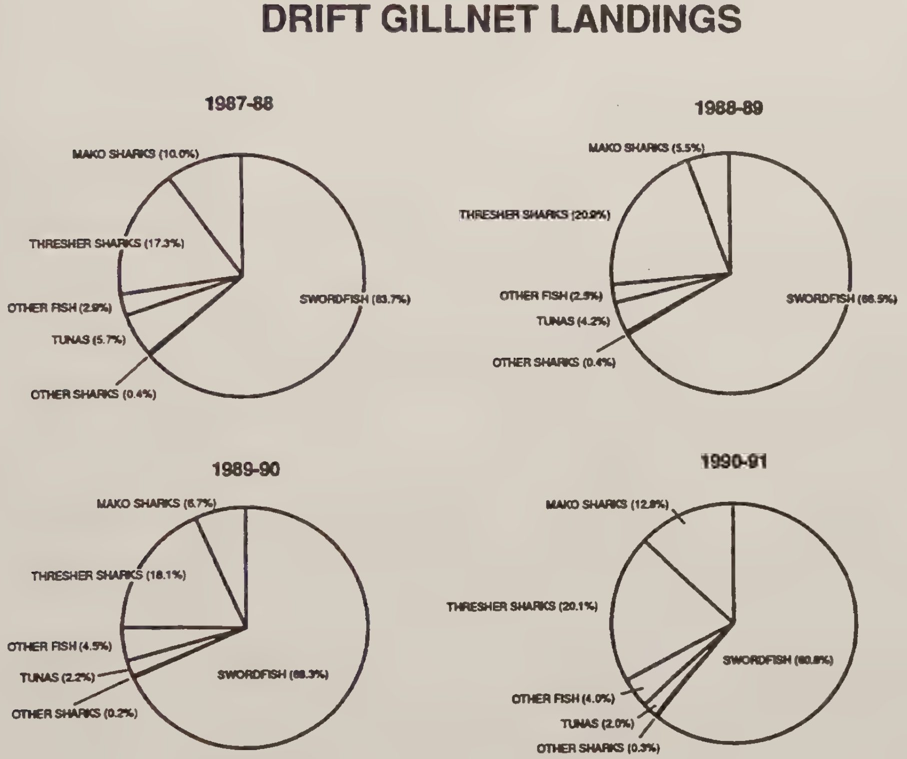

FIGURE 9b. Species composition of California drift gill net landings for the 1987-88 through 1990-91 fishing seasons.

Logbooks were collected from a majority of the drift gill net fleet and included data on most species caught, especially those that could be sold. Due to the volume of the data collected, this report will show seasonal and geographical distributions of only the four major species groups: swordfish, thresher sharks (common, pelagic, and bigeye), shortfin mako, and opah.

Coverage rates (proportion of landed fish weight reported in the logbooks) were determined by converting logbook catch to weight (number of fish times mean weight) and dividing by the corresponding weight reported on the landing receipt. Coverage rates in the 1981-82 season were very low, 6% for swordfish, 1% for thresher sharks, and 1% for shortfin makos. This was probably due to the newness of the logbook program that contributed to a low logbook return rate and possibly some deliberate misreporting of landings. Coverage rates for other

FIGURE 10. Current California Department of Fish and Game logbook used to record catches and fishing effort of drift gill net vessels.

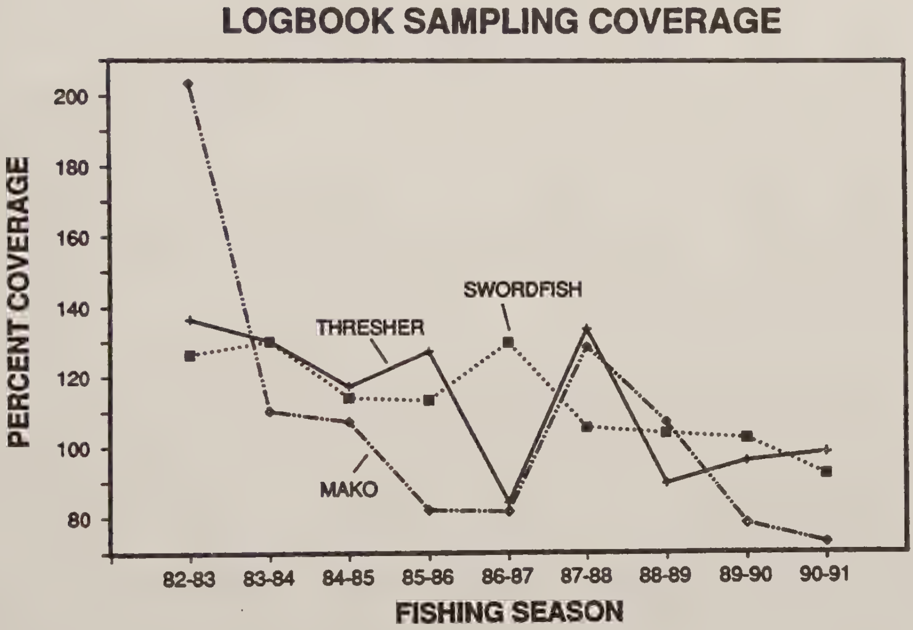

FIGURE 11. Coverage rates for drift gill net logbooks, 1982-83 through 1990-91. Rates are calculated as logged catch/landed weight. Coverage rates for the 1981-82 season were unusually low (6% for swordfish, 1% for common thresher and shortfin mako) and have not been included.

years for each of these species were almost always greater than 100% (Figure 11). Coverage rates over 100% may have been caused by overestimates in the reported logbook catches, or our calculated mean weights may have been biased high and overestimated actual landings. Also, landing receipts with an incorrectly recorded gear code (whether an inadvertent mistake or a conscious effort to subvert catch-ratio regulations) may not have been included in the summaries of drift gill net-caught fish.

### *Swordfish*

Logbook data closely followed landings data showing a peak in the catch during the 1984-85 season of 26,000 swordfish and a decreasing trend to 9000 swordfish in the 1990-91 season (Figure 12a). Catches of swordfish usually began in May to July in each fishing season, peaked in October and November and tapered off in December and January of the following year (Figure 12b).

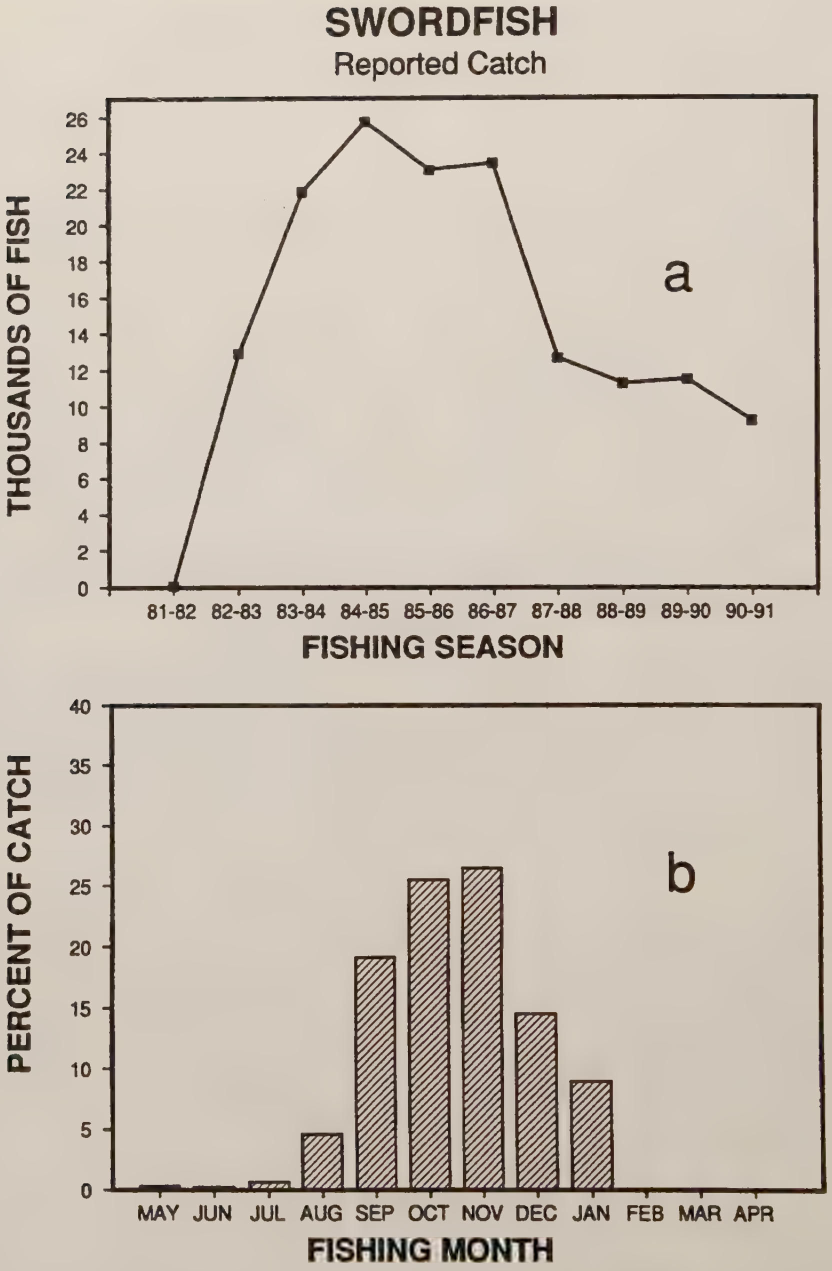

FIGURE 12. Logged catch of swordfish in number of fish by fishing season, 1981-82 through 1990-91 (a) and logged catch by month, all fishing seasons combined (b).

Swordfish were caught mainly in waters between San Diego and San Francisco and within 300 miles of shore (Figure 13). During the 1981-82 and 1982-83 seasons, areas of highest catches were off San Diego and expanded to include some areas around the Channel Islands during the following seasons. Small numbers of swordfish were also caught in areas between San Francisco and the California-Oregon border and within 120 miles of the shoreline. Some catches occurred farther north off Oregon and Washington, but because in some seasons the exact positions were not reported (designated only as off Oregon), they are depicted here in a 1° square at lat. 40° to 41° N (Figure 13).

## *Common Thresher*

The catch of common thresher reported on logbooks in 1981-82 was only 1000 fish, while landings exceeded 2 million lb. In 1982-83, logbook-reported catches climbed to over 20,000 fish and remained relatively high through the 1985-86 season (Figure 14a). Beginning with the 1986-87 season, the Legislature reduced the drift gill net thresher shark fishery to 30 days in May. As a result, mean catches of common thresher dropped to 6000 fish per season. In 1990-91, the Legislature closed the spring drift gill net fishery within 75 miles of shore, thus eliminating the directed thresher shark fishery in California.

When not restricted by closures, the highest proportion of catch was reported during May and June with 50% of the annual catch taken during these 2 months. The remainder of the catch was taken as incidental catch as the drift gill net fishery targeted swordfish during the summer and fall months. During the 10-year period, total catch varied somewhat between seasons, although the rate fluctuated little after the initial months of May and June (Figure 14b).

During the first years, most of the catch of common threshers was concentrated within the Southern California Bight. As the fishery expanded northward in 1982, catches off San Francisco (and north to about the Mendocino Ridge) became an important component of the total catch (Figure 15). A few drift gill net vessels fished Oregon and Washington waters near the Columbia River in 1986 and 1987 and landed 58,000 lb of common thresher in California. An additional 890,000 lb, landed in Oregon and Washington during these 2 years (Stick and Hreha 1988), are not included in our analyses.

## *Pelagic and Bigeye Threshers*

During the 10 fishing seasons 1981-82 to 1990-91, only 624 pelagic and 1891 bigeye threshers were reported on logbooks, although more may have been misreported as common threshers. A high proportion of the pelagic thresher catch was reported for May (Figure 16). They were also frequently caught in October

through January. Bigeye threshers were caught in August to November with a peak in September (Figure 17). Catches of both species were concentrated in the southern areas of the Southern California Bight (Figures 18 and 19).

## *Shortfin Mako*

Reported catches of shortfin mako peaked in the 1982-83 season at 19,500 fish and again in the 1986-87 season at 13,500 fish (Figure 20a). The 1981-82 reported catch (299 shortfin makos) was apparently low, because landings of 250,000 lb were reported on landing receipts. Average catch in the remaining years was just over 9300 fish or about 318,000 lb. Between the 1981-82 and 1988-89 seasons, shortfin makos were caught incidentally to thresher shark and swordfish from May to January, although the greatest portion was taken during July through September (Figure 20b). The proportion of catch in May declined substantially after the 1989 drift gill net fishing closure within 75 miles of shore during the spring. Overall, catches for the 10 years of data peaked in August and declined through winter months (Figure 20b).

Greatest shortfin mako catches were reported within the Southern California Bight. Sparse catches were recorded northward to about San Francisco in the early years following the 1982-83 season. Shortfin mako catches were rarely reported north of Cape Mendocino or beyond 200 miles from shore (Figure 21).

## *Opah*

Logbook catch data for opah closely followed landings data and showed peaks of 4300 fish in the 1984-85 season and 4100 fish in the 1985-86 season. After 1986, opah catches declined to a low of 600 fish in the 1988-89 season, then increased to 1300 fish in the 1989-90 season and 1100 fish in the 1990-91 season. Monthly catch summaries peaked in May (Figure 22), especially during the 1986-87 and 1988-89 seasons when 46% to 49% of the catch was reported in May. For the balance of the year, catches were rather evenly distributed during June to January with a peak in August. Opah catches occur throughout the range of the fishery, but are highest in the south (Figure 23).

## SIZE COMPOSITION

The CDFG began a program in 1981 to sample the landings of drift gill net vessels as catches were unloaded at commercial markets (Odemar 1982). Samples were taken at ports as far north as San Francisco and as far south as San Diego. While the majority of the samples were from catches made in the Southern California Bight, some samples were from catches made as far north as Oregon and Washington, as far south as the California-Mexico border, or as far as 250 miles offshore. Port samplers recorded lengths and weights of swordfish, thresher sharks, and shortfin makos (Figure 24). Sharks and swordfish were dressed at sea (headed and eviscerated), therefore lengths of these species measured at the wholesalers were alternate lengths (AL). Alternate length for swordfish was measured from the anterior margin of the cleithrum to the fork of the tail; for sharks, AL was measured from the origin of the first dorsal fin to the origin of the second dorsal fin (Figure 25). Measurements were taken with calipers to the nearest millimeter.

Lengths and weights, as well as other biological parameters (sex, pup counts, etc.), were recorded occasionally for other species (tunas, opah, louvar, etc.). Although size-composition samples were taken of many species of fish from landings at commercial fish markets, the vast majority of the samples were of swordfish, thresher sharks (common, pelagic, and bigeye) and shortfin mako (Table 4).

Size-composition coverage rates were estimated as the number of fish measured divided by the number of fish reported in logbooks. Coverage rates were highest for swordfish in all seasons except 1982-83 and 1989-90 when thresher sharks or shortfin mako were targeted by samplers (Figure 26). Swordfish samples rose from a low of 207 in the 1981-82 season to a high of 4972 in the 1986-87 season and dropped to 1029 in the 1990-91 season. The highest swordfish size-composition coverage rates (28%) were obtained during the 1988-89 season. Common thresher samples decreased from a high of 1568 in the 1983-84 season to a low of 665 in the 1987-88 season. Common thresher size-composition coverage rates were highest during the 1989-90 season. Shortfin mako samples rose from a low of three in the 1981-82 season to a high of 1097 in the 1989-90 season; size-composition coverage rates were highest during the 1989-90 season. Size-composition coverage rates estimated for the 1981-82 season were unrealistically high for swordfish (356%) and thresher sharks (106%) due to low logbook coverage rates. Coverage rates for shortfin mako were 1% for the 1981-82 and 1982-83 seasons.

## Swordfish

The sizes of swordfish sampled during the 1981-82 through 1990-91 fishing seasons (22,870 fish measured) ranged from 37 to 250 cm AL with a mean of 144 cm AL (Table 4; Figure 27). Fish reported as less than 47 cm were considered errors in measurement or measurements of shark-damaged fish and were not included in our summaries. The bulk of the measurements were between 100 and 195 cm. By year, the means varied between 128 and 152 cm, with peaks in

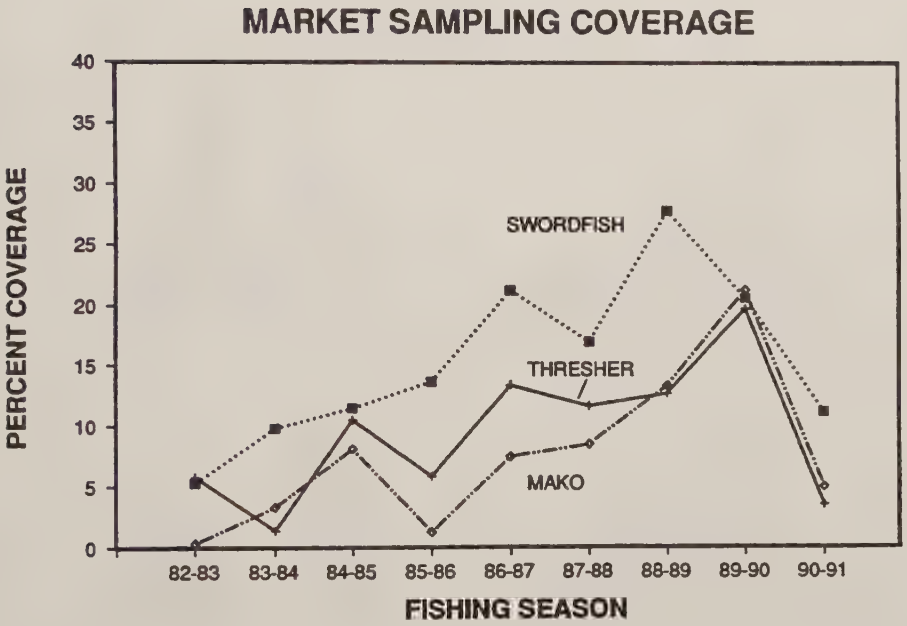

FIGURE 26. Coverage rates for market sampling of swordfish, common thresher, and shortfin mako. Coverage rates for the 1981-82 season were unrealistically high for swordfish (356%) and common thresher (106%) due to low logbook coverage rates, while shortfin mako rates were at 1% and are not presented.

1982-83, 1985-86, and 1988-89 (Figure 28). Larger swordfish (150 to 160 cm AL) tended to be caught off the northern California and Oregon coasts, with smaller fish (130 to 145 cm AL) taken farther south (Figure 29). The primary mode of fish caught north of lat. 35°N tended to be 2 to 5 cm larger than that of fish caught south of that line. Also, the average weights of fish caught north of lat. 35°N were as much as 17 kg (dressed weight) more than fish caught farther south. Swordfish caught during June to December tended to be larger (140 to 155 cm AL) with the largest caught in August (Figure 30). Smaller swordfish (100 to 135 cm AL) were caught during January to May, although sample sizes in these months were relatively low. Length-to-age conversion tables revealed that the majority of the sampled catch was immature swordfish 3 to 5 years old.

## Common Thresher

During the 10-year period covered, port samplers measured a total of 9646 common threshers ranging from 12 to 136 cm AL with a mean of 60 cm AL (Table 4); most ranged between 40 and 80 cm AL (Figure 31). The alternate length for common thresher represented approximately 17.5 percent of the total length. The means were 65 and 68 cm AL, respectively, for the 1981-82 and 1982-83 seasons, which were fished primarily in the Southern California Bight. The mean length of common threshers peaked in the 1982-83 season at 68 cm AL and steadily declined to a low of 51 cm AL in 1989-90 (Figure 32) even though the drift gill net fishery expanded into previously unfished areas. The size of maturity was estimated at 333 cm TL (56 cm AL) for males and 390 cm TL (75 cm AL) for females (Cailliet and Bedford 1983). Length frequencies indicate that a majority of the catch were immature sharks; mature adults, especially females, represented only a small percentage of the landings during any of the fishing seasons.

As the fishery expanded northward, larger sharks were caught. Common threshers from north of lat. 36°N ranged from 50 to 98 cm AL (Figure 33). In the 1986-87 and 1987-88 seasons off Oregon and Washington, most common threshers caught were adult. A large number of those were males and averaged 76 to 79 cm AL (Stick and Hreha 1988). A small portion (16 individuals) of the Oregon and Washington catch was measured in California and had a mean AL of 75 cm with a range of 63 to 99 cm AL. The range of sizes for common threshers sampled from the lat. 32° to 35°N bands was similar, although those from off San Diego may tend to be somewhat larger (Figure 33). Common threshers caught during July, August, and September tended to be larger (mean AL = 60 cm to 65 cm.; Figure 34). A higher percentage of smaller fish are taken in October, November, and December.

## Pelagic and Bigeye Threshers

Only 116 pelagic and 468 bigeye threshers were measured during the 1981-82 through 1990-91 fishing seasons (Table 4; Figure 35). The small sample sizes are possibly due to misidentifying and recording these species as common threshers. Both species are similar in size to the common thresher and can be difficult to distinguish when cleaned and dressed for market. No trends by season or catch location were apparent for either species.

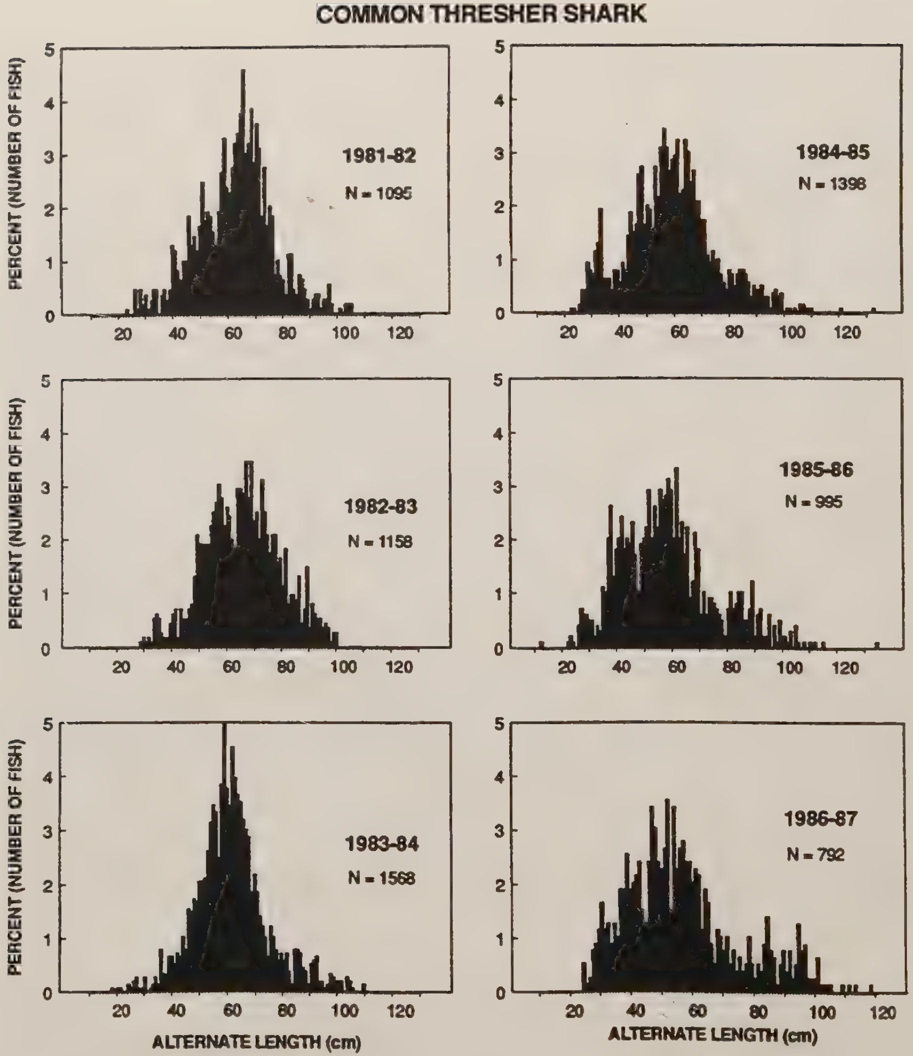

FIGURE 31a. Length-frequency distribution of common thresher sampled at California markets during the 1981-82 through 1986-87 fishing seasons.

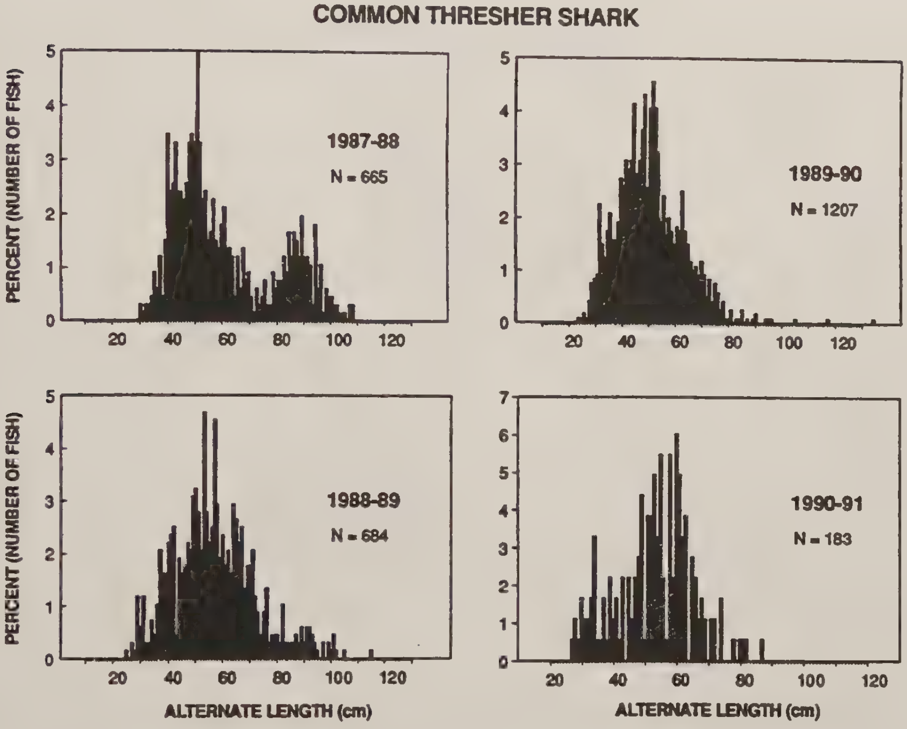

FIGURE 31b. Length-frequency distrbution of common thresher sampled at California markets during the 1987-88 through 1990-91 fishing seasons.

## Shortfin Mako

A total of 5659 shortfin makos were sampled by the CDFG during 1981-82 through 1990-91. Length measurements ranged from 6 to 134 cm AL (Table 4; Figure 36) with a mean of 47 cm AL. Reported lengths of fish less than 20 cm are suspect and are probably erroneous measurements. The mean length declined from 58 cm AL in 1982-83 to less than 35 cm AL in 1985-86, then averaged about 47 cm AL over the next 5 years (Figure 37). Length distributions for the 1982-83 and 1985-86 seasons may unrepresentative due to the small sample sizes and limited area (south of Point Conception) and season (late October and early November) of coverage.

There was a trend towards larger shortfin makos in the northern areas (Figure 38). Shortfin makos caught south of San Diego (the lat. 32°N band and south) had a mean AL length of 43 cm, while those off San Diego and Los Angeles had

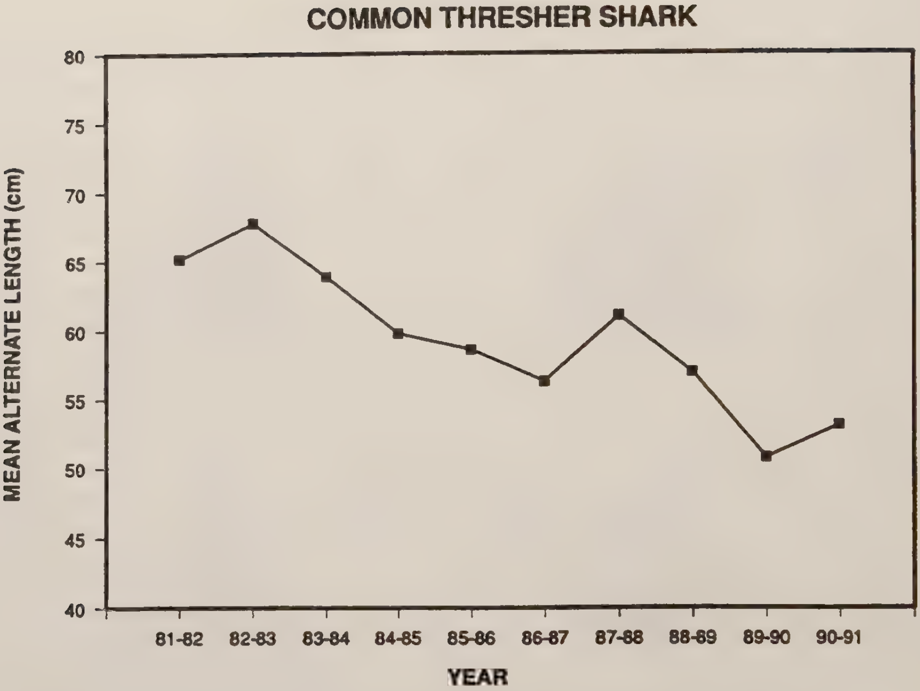

FIGURE 32. Mean alternate length of common thresher sampled at California markets, 1981-82 through 1990-91 fishing seasons.

a mean AL length of 49 cm. Shortfin makos sampled from the lat. 35° and 36°N bands (San Luis Obispo to Santa Cruz) had annual AL means ranging from 52 to 55 cm. Shortfin makos caught during May through August tended to be larger than those caught during October through December (Figure 39).

Alternate length of the shortfin mako shark represents about 34% of total body length. Because males mature at 195 cm TL (66 cm AL) and females mature at 280 cm TL (95 cm AL; Stevens 1983), it is clear that the catch was composed almost entirely of juveniles.

## Opah

During the period covered, 1967 opahs were measured and sizes ranged from 10 to 242 cm FL (Table 4; Figure 40). The majority of the lengths were centered in three modes at 80, 100, and 112 cm FL. Due to the small number of opahs measured, any difference between sizes of fish caught in the north and south were not evident.

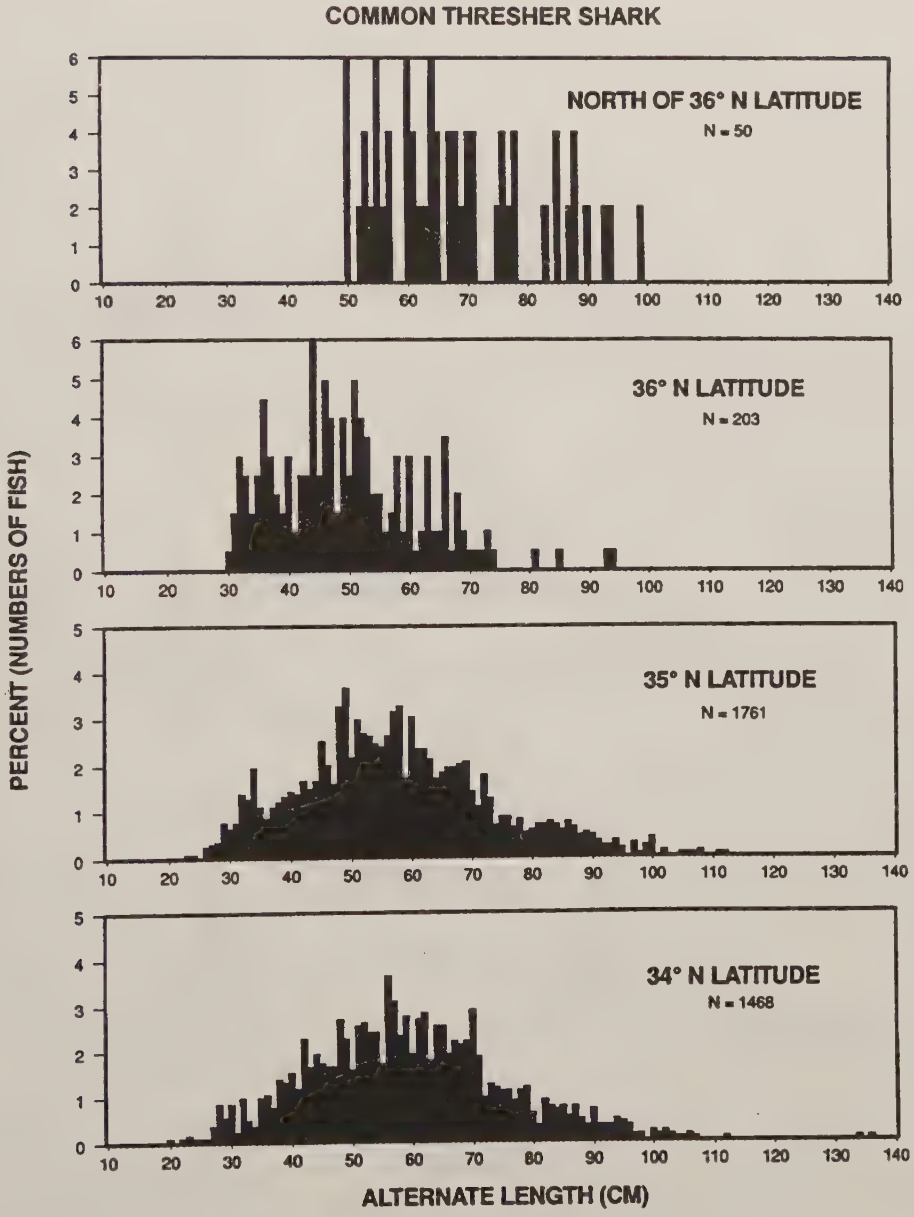

FIGURE 33. Length-frequency distribution of common thresher by latitudial bands of catch location, from California market samples, 1981-82 through 1990-91 fishing seasons.

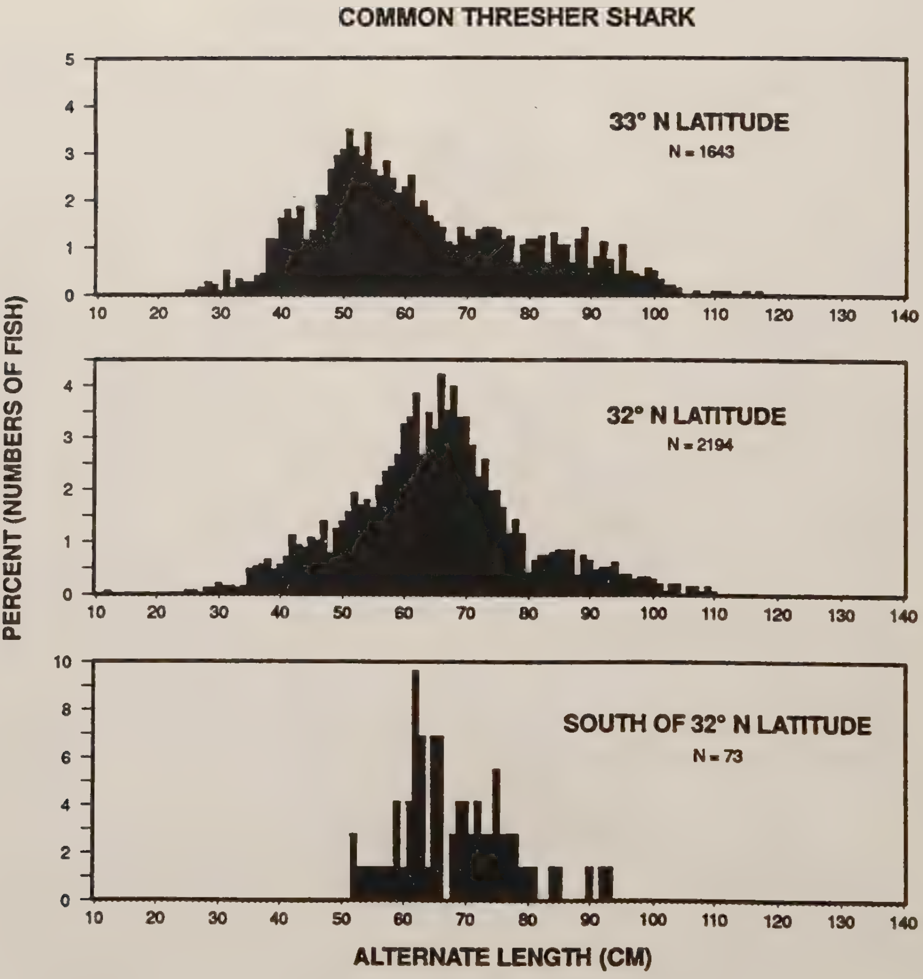

FIGURE 33. (continued)

# DISCUSSION

We have presented a description of the California drift gill net fishery, which evolved from a small nearshore experiment to a major California fishery. There have been major changes in nearly every aspect of the fishery including boats, gear, fishing techniques, regulations, fishing areas, seasons, and targeted species. We are particularly pleased with the manner in which we were able to incorporate both landing receipt and logbook data along with market samples to

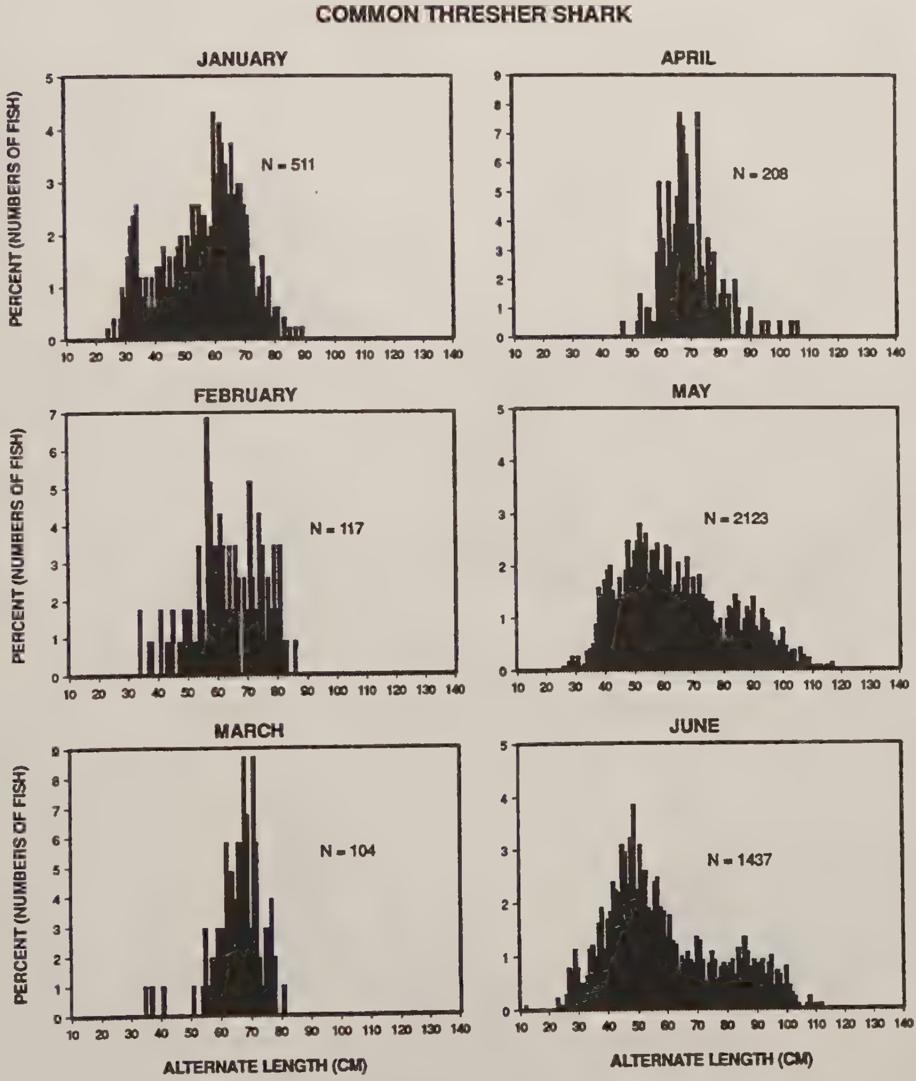

FIGURE 34a. Length-frequency distibution of common thresher by month, January to June, sampled at California markets during the 1981-82 through 1990-91 fishing seasons.

summarize important facets of the fishery. We encourage others to utilize these sources for further, more in-depth analyses of this fishery and related stocks.

We feel that the quality of all data collected for the drift gill net fishery, while relatively high in some areas, can be improved. We found some confusion in the way logbooks were completed, especially in the recording of catch. In some cases,

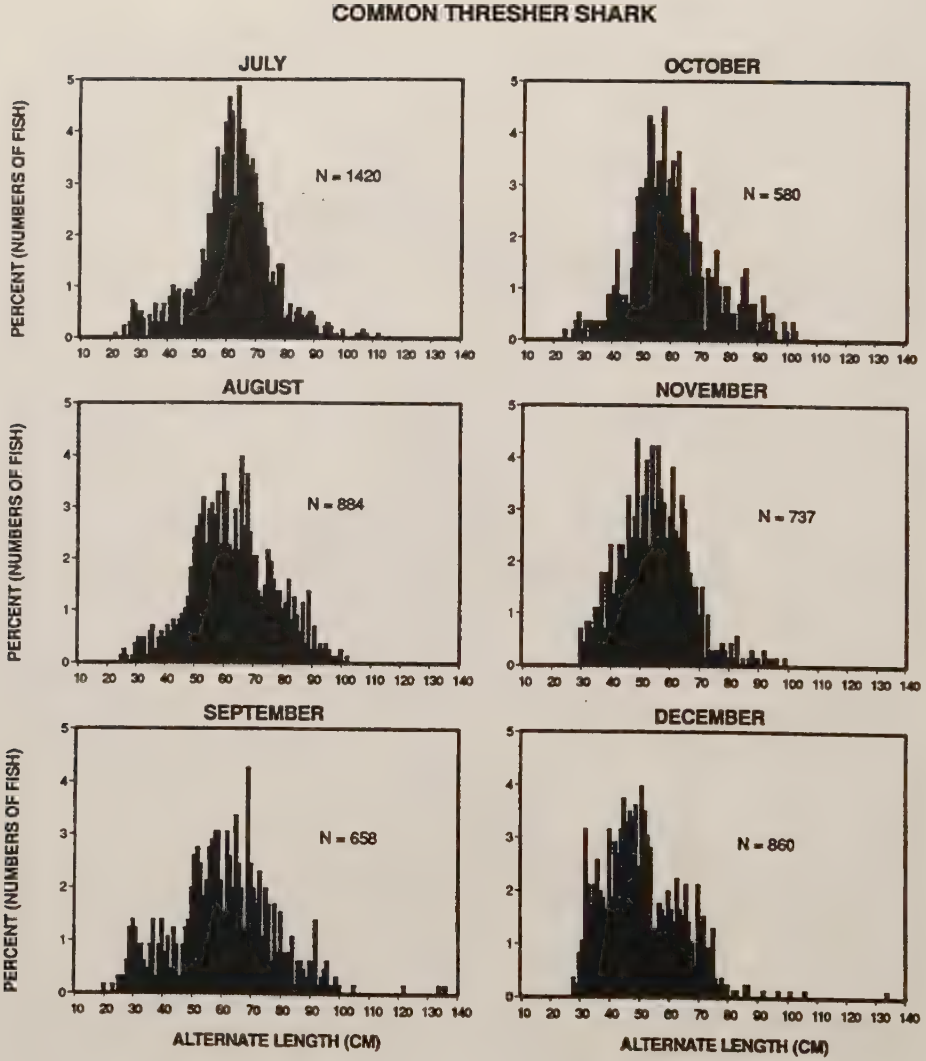

FIGURE 34b. Length-frequency distribution of common thresher by month, July to December, sampled at California markets during the 1981-82 through 1990-91 fishing seasons.

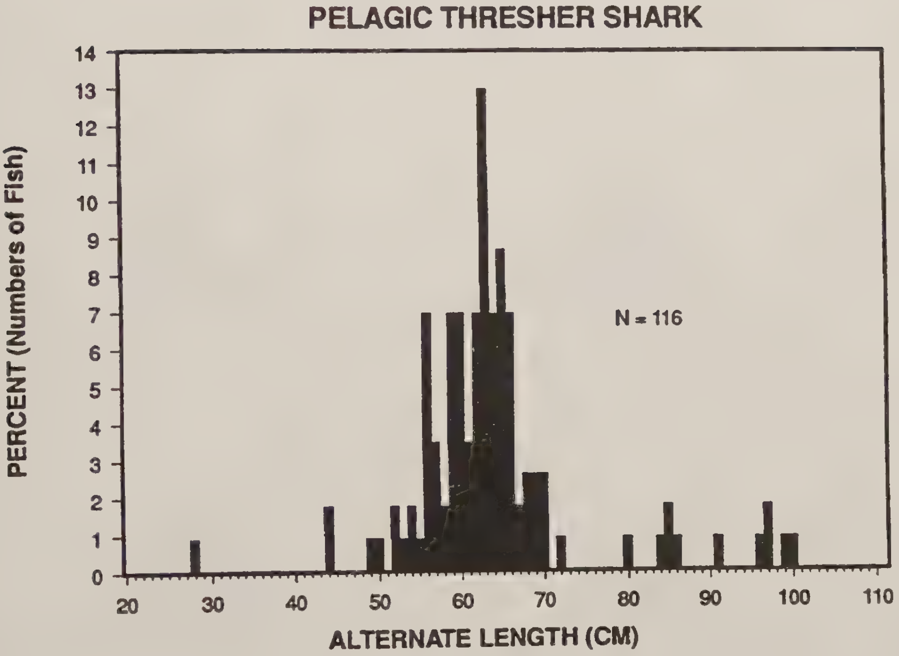
catch was reported by number, in other cases by weight, and many times without any indication of which units were used or if a combination of both was used. Much of this confusion could be eliminated if more complete instructions were provided with the logbooks. There was also some intentional misrepresentation such as miscoding of gear types on landing receipts and net-caught swordfish



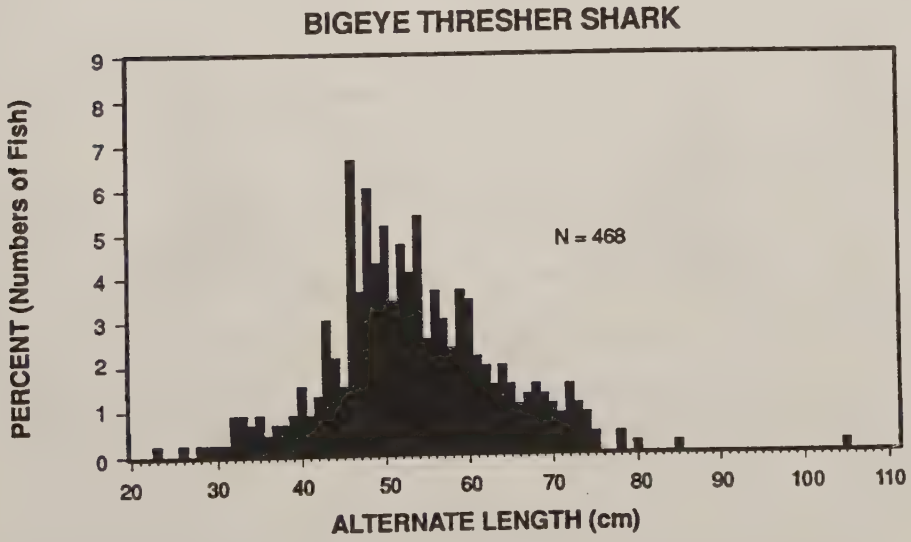


FIGURE 35. Length-frequency distribution of pelagic thresher and bigeye thresher sampled at California markets during the 1981-82 through 1990-91 fishing seasons.

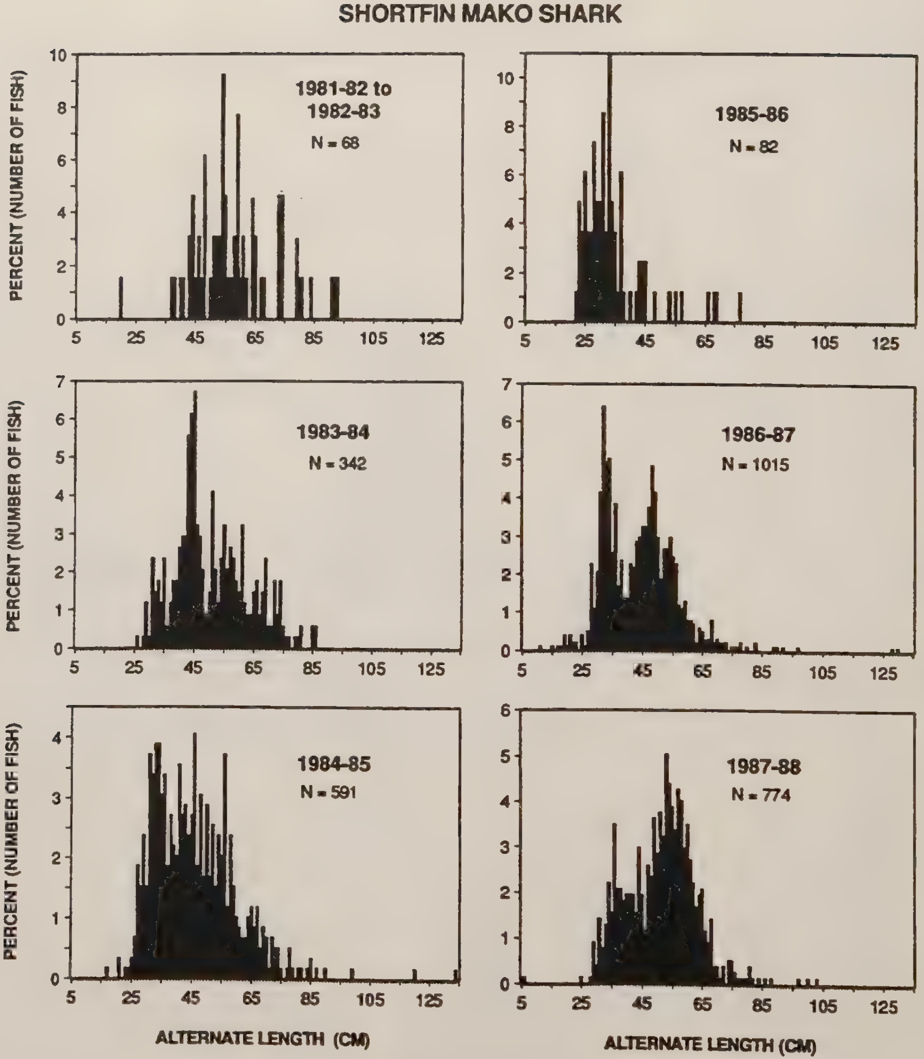

FIGURE 36a. Length-frequency distribution of shortfin mako sampled at California markets during the 1981-82 through 1987-88 fishing seasons.

stuck with a harpoon after capture (especially during the period when swordfish landings from drift gill net gear were not allowed to exceed shark landings).

Coverage rates of the market sampling system for sizes of fish are comparable to other fishery sampling programs. However, the adequacy of this level of sampling is difficult to assess since no formal sampling plan exists. The quality of

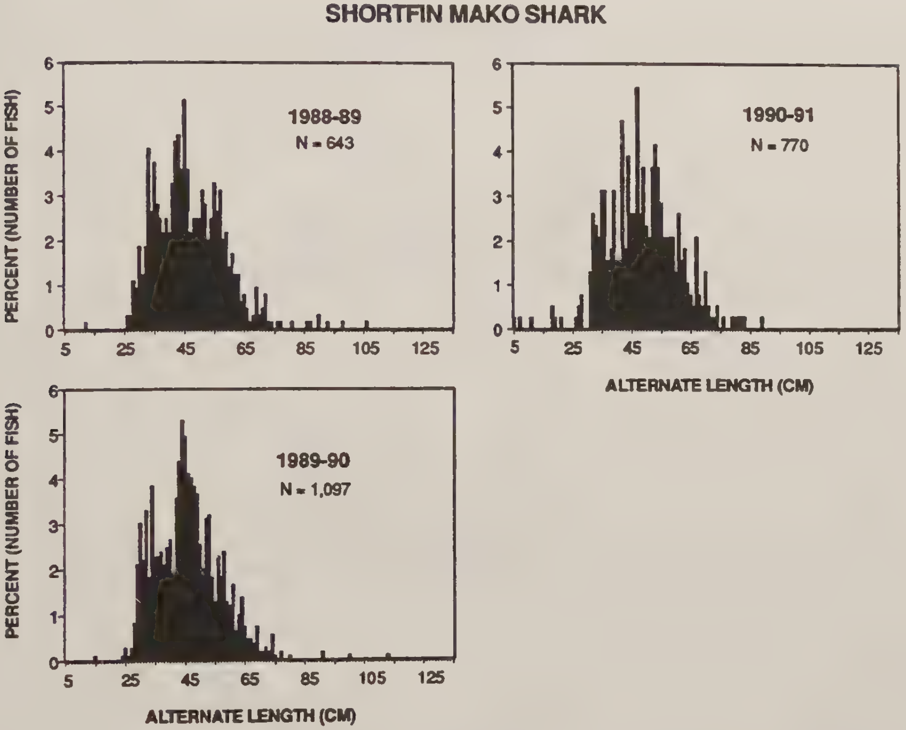

FIGURE 36b. Length-frequency distribution of shortfin mako sampled at California markets during the 1988-89 through 1990-1991 fishing seasons.

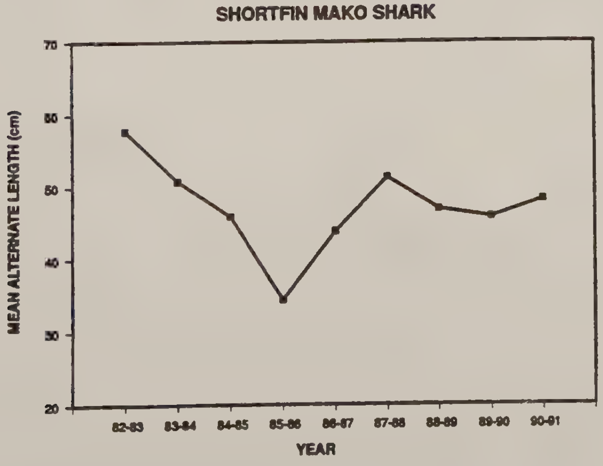

FIGURE 37. Mean alternate length of shortfin mako sampled at California markets, 1982-83 through 1990-91 fishing seasons.

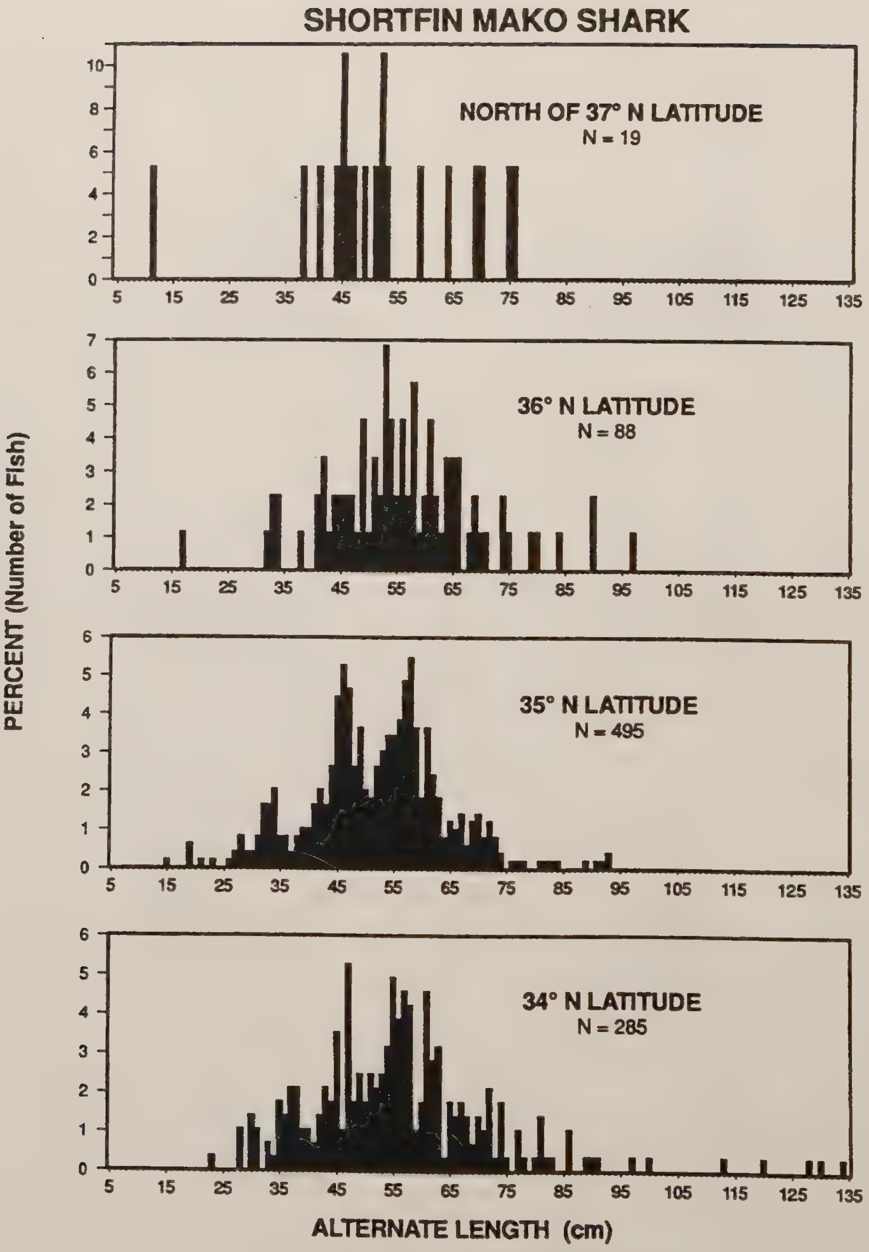

FIGURE 38. Length-frequency distribution of shortfin mako by latitudinal bands of catch location, from California market samples, 1981-82 through 1990-91 fishing seasons.

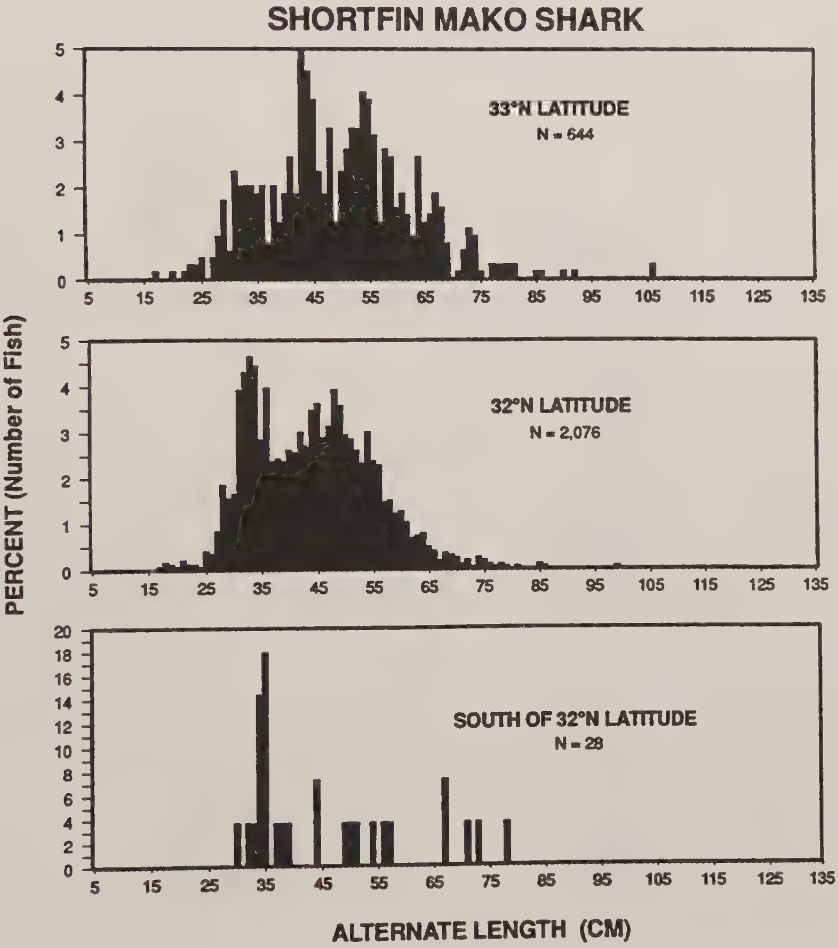

FIGURE 38. (continued)

length data may be improved by the establishment of a formal sampling plan which would evaluate sample sizes by species and month of landing.

We made major assumptions to separate landings between set gill net and drift gill net gear, because many landing receipts did not distinguish between the two nets and reported gear type only as gill net. These assumptions may have biased estimates of landings for some species and may have biased estimates for number of vessels using drift gill nets. While we feel that these biases are relatively low, a revision of landing receipts to allow for separate entries for drift and set gill nets as well as instructions explaining the problems in separating these catches

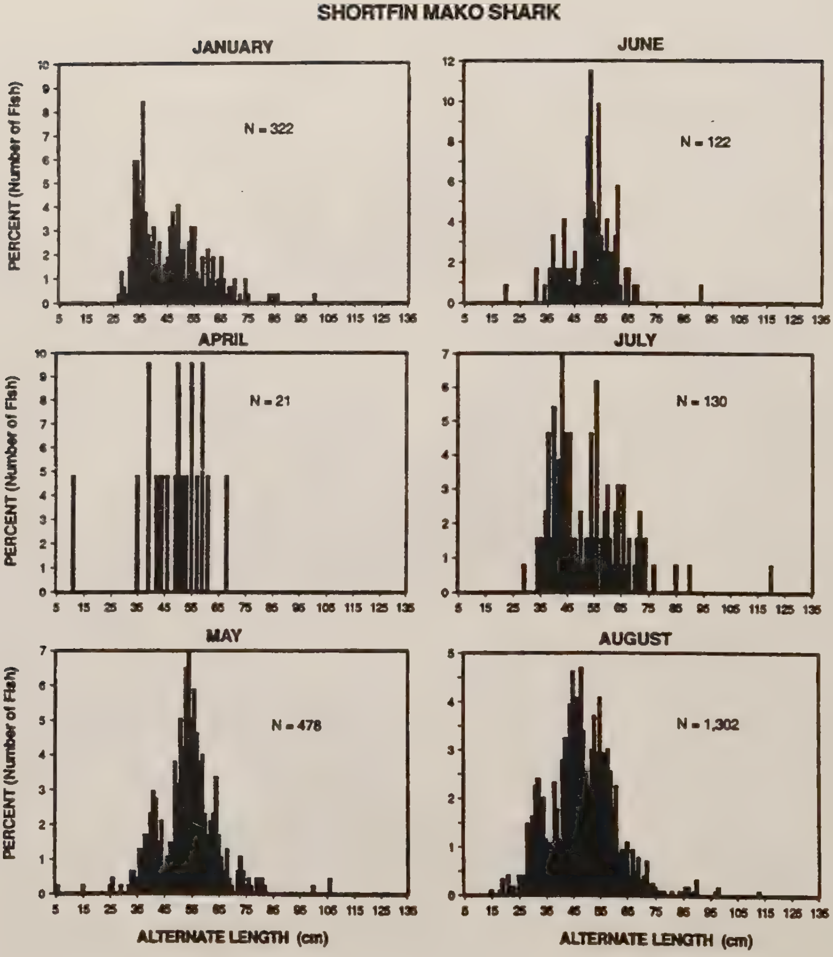

FIGURE 39a. Length-frequency distribution of shortfin mako by month, January to August, sampled at California markets, 1981-82 through 1990-91 fishing seasons.

and soliciting compliance in accurately entering the gear type would eliminate the need for many of these assumptions and increase the quality of the landings data.

This study summarizes the pertinent available data obtained from the California logbook system, landing receipts, and market sampling. These data form a base line from which changes in the fishery and harvested stocks can be com-

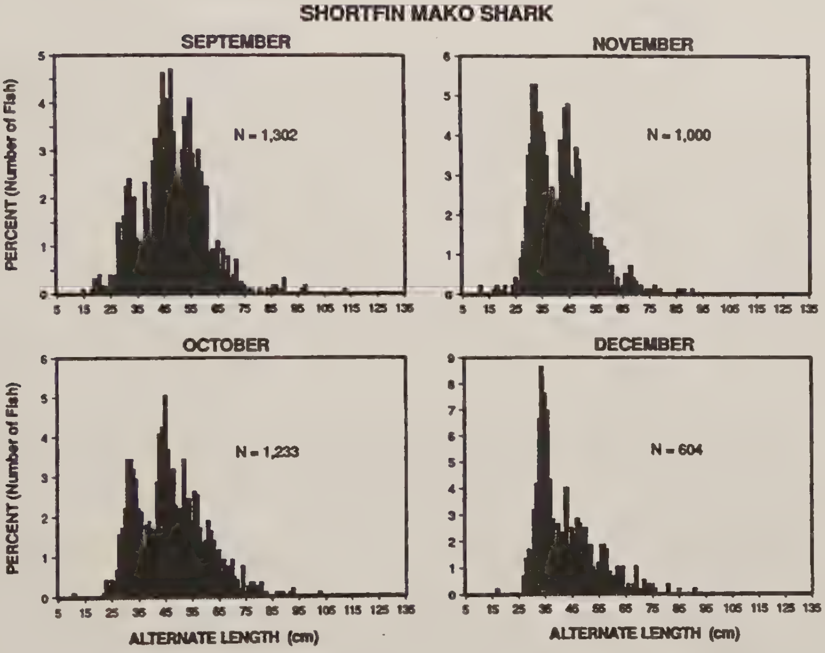

FIGURE 39b. Length-frequency distribution of shortfin mako by month, September to December, sampled at California markets, 1981-82 through 1990-91 fishing seasons.

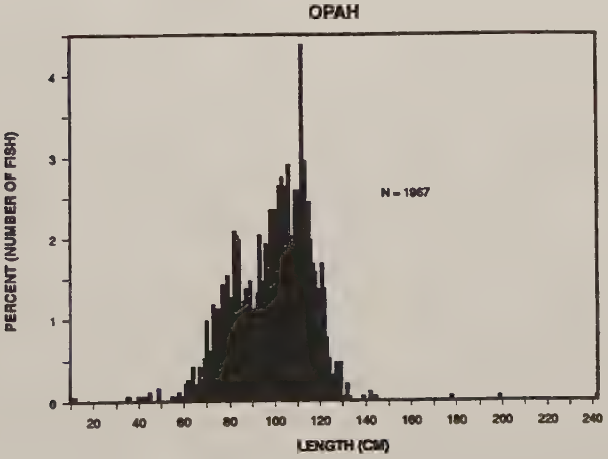

FIGURE 40. Length-frequency distribution of opah sampled at California markets, 1981-82 through 1990-91 fishing seasons.

pared in the future. More detailed analyses of trends in the fishery and the resources should follow.

We have shown that the California drift gill net fishery operated primarily in the area between San Diego and Cape Mendocino, concentrating on swordfish in the Southern California Bight during the months of May to December.

Since the 1985-86 fishing season, fishing effort has decreased 50% to 60% and the decreasing effort corresponds to decreasing total landings of the same proportions. Both decreases are due in part to the spring fishing closure for sharks. Decreases in landings of common thresher were over 80%, while swordfish and shortfin mako landings decreased 60% and 40%, respectively. Sizes of swordfish showed no increasing or decreasing trend. Mean sizes of common thresher decreased 21% from the 1982-83 season to less than 55 cm AL in the 1990-91 season. There was no significant change in the mean size of shortfin mako, although a small sample size in 1982-83 and nonrepresentative sample in 1985-86 were responsible for a seeming decrease during the period we examined (Figure 37).

The decreases in landings can be directly related to decreased fishing effort. However, the corresponding decreases in mean size of common thresher may indicate a problem within this population or that the fishery does not operate at the times or in the areas when big fish are present. We therefore recommend that further investigations including catch per unit effort be conducted for the major species caught by this fishery.

There have been a number of problems and conflicts that have occurred during the first 10 years of the fishery (e.g. sea lion, gray whale, and marlin bycatch). These have been addressed and resolved interactively through the cooperative efforts of the commercial industry, the recreational fishing industry, environmental groups, and State and Federal governments. These efforts, which included many specific, problem-oriented time and area restrictions, resulted in an overall reduction in fishing intensity and the bycatch of marine mammals.

Concerns regarding the drift gill net fishery are similar to those expressed when the fishery started. Specifically, shark fisheries throughout the world historically have not been sustained and in fact, tend to decline significantly or crash rather suddenly (Compagno 1990). Shortfin makos and common threshers taken by the California drift gill net fishery within the Southern California Bight are primarily juveniles. In response to declines in the quantity and size of common thresher caught, the State virtually eliminated the directed fishery with area and season closures. If the number and size of shortfin makos caught should also decline, similar management controls may be warranted.

In the early 1980s, the incidental catch of marine mammals was relatively high, but time and area closures around the Channel Islands and along the mainland apparently were successful in reducing that catch. Currently, the incidental catch of marine mammals in this fishery is apparently not compromising any stocks, but the potential for a significant bycatch remains and may involve some species listed under the Endangered Species Act. Thus, continued monitoring, as with the NMFS mandatory observer program, is prudent.

Bycatch of fish does not appear to be a problem except possibly for blue sharks which are caught but not utilized. As this catch is not reported or monitored, it might also be a significant problem in determining the status of local populations. Important changes in abundance may not be detected in time to make prudent management decisions. Because fishing mortality and stock status of blue shark are unknown, close monitoring of the commercial as well as recreational fisheries is warranted.

## ACKNOWLEDGMENTS

The efforts of Marilyn Beeson (CDFG), Corrin Holder (CDFG), Doug Prescott (NMFS), Laura Halko (NMFS), Cheryl Brown (NMFS), and John Childers (NMFS) to organize and prepare the data used in this bulletin are gratefully appreciated. We thank Ken Raymond for producing the extensive graphics. John Sunada and the CDFG Market Fisheries Unit are thanked for making the market sampling data available.

Dennis Bedford (CDFG) is recognized for development of the CDFG observer program and initiating many of the drift gill net research activities. His helpful suggestions improved the manuscript. Tony West (California Gillnetters Association) was generous in sharing his knowledge of the fishery.

Richard Klingbeil (CDFG), Dr. Gary Sakagawa (NMFS), Dr. Norman Bartoo (NMFS), Dr. Jay Barlow (NMFS), John Sunada (CDFG), Gene Fleming (CDFG), and Dr. Christopher Dewees (California Sea Grant Extension Program) are thanked for critical manuscript review. Portions of the funding for this work were provided by cooperative agreements Nos. NA89AB-H-MM036, NA86-ABD-00201, and NMFS Data Rescue Funding.

# An Overview of Guam's Inshore Fisheries

REBECCA A. HENSLEY and TIMOTHY S. SHERWOOD

The authors are with the Division of Aquatic and Wildlife Resources, Government of Guam, P.O. Box 2950, Agana, Guam 96910. Correspondence to them may be addressed as follows: R. A. Hensley, Texas Parks and Wildlife Department, 1231 Agnes St., Corpus Christi, TX 78401; and T. S. Sherwood, 3245 Austin Dr., Colorado Springs, CO 80909. Views of opinions expressed or implied are those of the authors and do not necessarily represent the position of the National Marine Fisheries Service, NOAA.

*ABSTRACT—Guam's nearshore reef fishery is a multi-gear, multispecies fishery that has undergone major changes through the years. Methods have evolved and become more modern. This, along with the changing economic status of Guam, has severely stressed the fishery. Top targeted species are being overexploited and "growth overharvesting" is occurring; the more serious form of "recruitment overharvesting," is happening to some of the key species. Major management concerns are discussed with respect to overfishing and habitat destruction. Management recommendations for this fishery include gear restrictions, size restrictions, and the establishment of marine conservation areas.*

## Introduction

### Background

Since long before the first contact of westerners with native Guamanians (or Chamorus[1]) in 1521, fish has been the primary source of protein for the islanders. Little is known about traditional management of Guam's fisheries, but fishing was and has remained an important part of life and culture. In the past, subsistence fishing provided Guam's residents with an ample supply of fish. Most of the fish caught were consumed by fishermen's families or shared with the community and were harvested from three main areas of the sea: The coral or nearshore shallow adjacent areas, nearshore slopes to about 100 fathoms and the surface ocean waters. Much of the traditional use of fish for social obligations in the form of fiestas (large gatherings for funerals, weddings, christenings) is still practiced.

Guam is a U.S. territory located in the western Pacific (Fig. 1). It is the southernmost and largest island in the Mariana Island Archipelago with over 130,000 people on about 550 km$^2$. Much of the change in Guam's fisheries, from traditional subsistence fisheries to the more modern subsistence, commercial, and recreational fisheries has occurred since World War II. Johannes (1978) maintained that the decline of the Pacific island fisheries was due mostly to change in the economic system of the Pacific Islands to a more western one which has eroded the ancient marine tenure laws and tra-

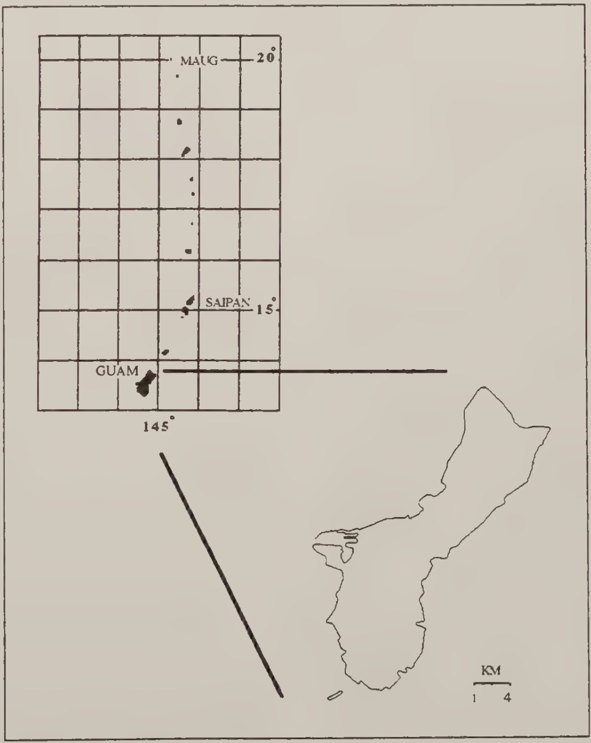

Figure 1.—Guam (13°30'N; 144°50'E) is the southernmost of the Mariana Archipelago.

---

[1] Chamoru, previously Chamorro, is the currently accepted spelling of the indigenous people of Guam.

ditional island conservation ethics. This, along with the introduction of more modern, manufactured fishing materials (monofilament nets, steel hooks, poles, reels, spearguns, scuba gear, etc.), has changed the complexion of Guam's inshore fishery and aided in the decline of the nearshore reef fishery. Ikehara et al. (1970) stated that Guam's shallow inner reefs appeared to be fully exploited and showed signs of overfishing. Katnik (1982) found that two heavily fished areas on Guam were overfished and stated that other accessible areas on Guam could be equally overexploited. What was once a well stocked, complex fishery with diverse fishing methods has changed to a fishery under serious fishing pressure.

### Scope

Because of the increased efficiency of fishing techniques due to introduction of modern materials and because of the increase in fishermen and the island population, the Guam Division of Aquatic and Wildlife Resources (DAWR) recognized the need to protect the fishery from overharvesting. Initial monitoring of the resources began in the 1960's, and it had evolved by 1982 into the current creel survey methodology adapted from Malvestuto et al. (1978). Because of the different usage and the different areas of the sea utilized for the multispecies, multigear fisheries, Guam's fisheries monitoring was divided into two projects. These were the "inshore" (or nearshore reef ) fisheries and the "offshore" (small boat) fisheries (Myers, 1993). The inshore fisheries discussed here will encompass the coral or nearshore shallow adjacent waters which consists mostly of fringe reefs.

This paper describes inshore fisheries, concentrating on data from 1982 through 1991. We discuss fishing techniques and data collection and compilation for landing and effort estimates of Guam's fishery. The harvest components (finfish, nonfinfish, and seasonal juveniles or traditional fishery) and current management practices are described with suggestions for conservation of the fishery.

## Guam's Inshore Fisheries

### Historic Fishing Methods

Detailed fishing techniques from prehistoric times have been described by Amesbury et al. (1986) and will be only briefly described here. Early fishing techniques (prior to the 1930–40 period) employed gear composed of natural materials. Today, inshore (or reef and lagoon) methods have incorporated modern equipment and have been modified in some manner from the traditional form of fishing. Some form of hook and line fishing, usually handline, has been done since the arrival of the Chamorus on Guam around 1500 BC (Amesbury et al., 1986). Net fishing has included forms of dip netting, bag seining, throw netting, surround netting, drag netting, and gill netting (a more recent form of net fishing). Fishing with traps and spears has occurred throughout the history of Guam. Women historically harvested the seagrass parrotfish (Scaridae) and some wrasses (Labridae) by hand. All social classes of Chamorus harvested eels with iron spears and crabs with multipronged spears. Gleaning for invertebrates has always occurred, especially for mollusks and algae for use as either bait or food. The Spaniards gleaned for sea cucumbers.

Several types of fishing no longer occur. Two of these are the opelu or hachuman fishing (for *Decapterus* sp.) and the decoy method of fishing (Amesbury et al., 1986). Turtles were harvested until 1976 when it was prohibited. Other currently prohibited methods include fish weirs, fish poisoning from root extract (*Barringtonia asiatica* tree), chlorine bleaching, and dynamiting. These are still practiced illegally on a small scale.

Traditional fishing practices are still observed routinely on Guam. One practice is the fishing for seasonal juveniles recruiting to the reef flats (discussed below), while the other practice involves sharing the catch. The catch from the surround net or chenchulu (when used for catching seasonal mackerel or *Selar crumenopthalmus*) is still divided up into thirds with the portions going to the owner of the net, the village where the fish were caught, and those who helped harvest the catch.

### Contemporary Fishing Methods

Many of the currently used methods are very efficient because the technology and materials used are readily available at a minimal cost. Contemporary methods include hook and line, net fishing (cast, gill, drag, and surround net), spear fishing (snorkel and scuba), hook and gaff, and "other" methods (a miscellaneous category that includes mostly gleaning for invertebrates). These methods, modified through time, are described below and account for the harvest of over 100 species of finfish and 40 nonfinfish species (3 lobster, 9 crab, 24 mollusk, and 4 echinoderm)[2] (Amesbury et al., 1986, 1991).

Currently, the most popular fishing method on Guam is hook and line. This technique ranges from the use of handlines to rod and reel with lures or baited hooks. Recently, we have observed fly fishing in Guam's waters.

The majority of the fish harvested are taken by net fishing. All types of net fishing done today, except gill netting, have long histories on Guam. Net mesh sizes range from 1/4-inch stretch (for seasonal juveniles) to greater than 3-inch stretch. The cast net or throw net (talaya) is one of the few nets that are still hand woven (using monofilament) by the traditional talaya fishermen[3]. These nets vary in mesh size and number of pockets depending on the fish targeted.

Other than the modern equipment, drag netting has changed very little through time. It still is the simplest form of net fishing where the net is pulled through the water as the fish are driven into the net. Today, this method is most often, but not always, used at night.

---

[2] This identifies all information, unless otherwise cited, obtained by the authors from Guam Fisheries Investigations-Project FW-2R-26 Job Progress Reports (Jobs: F-F1–2 Inshore Fisheries Survey; F-F1–3 Fisheries Data Processing; F-F1–8 Studies of Recreationally Important Reef Fish). Information can be obtained from the Division of Aquatic & Wildlife Resources (DAWR), Dept. of Agriculture, P.O. Box 2950, Agana, Guam 96910.

[3] D. Narcissi, Talaya fisherman, Guam Environmental Protection Agency, Harmon, Guam 96912. Personal commun.

The use of the surround net or chenchulu has occurred for many years. Today, two types of surround netting occurs. In the first type, two people transport the net through the water on two large inner tubes. The fishermen begin setting the net in a 'U' shape and close the net into a circle as a second group of people drive the fish into the net. Once the net is set, the fishermen dive into the enclosure and harvest the fish by spear and/or hand. The second form of the surround net, also called the atulai gill net (Amesbury et al., 1986), is one that is used to harvest seasonal mackerel or atulai. This net is most commonly used in the harbors, channels, or bays. When a school of atulai is sighted, a boat surrounds the fish with the net and the school can be harvested over a period of days.

Gill net fishing is the most recent form of net fishing on Guam. This method is very popular (usually ranking in the top three of all methods used). This popularity is due to the availability of the gill nets, the comparative low cost, and the effectiveness of the modern monofilament materials. The net is used at any time of the day or night, but it is most successful on an ebb tide where fish escaping the shallows are gilled in the net.

Spearfishing has undergone a vast change with the advent of modern equipment, evolving from handmade spears and freediving to spearfishing with scuba gear. Spearfishing with snorkel and spearfishing with scuba target different fishes and are considered separate techniques. Because of the highly selective nature of both of these methods, spearfishing harvest consists of fish of larger species (i.e., humphead parrotfish, *Bolbometopon muricatum*) than other fishing techniques.

The remaining two methods are primarily used for harvesting nonfinfish. The use of hooks and gaffs targets octopus, although some mantis shrimp and miscellaneous fish are also caught. The last method, a catch-all category appropriately called "other," generally includes gleaning for nonfinfish. New or little-used techniques like dip netting and mantis shrimp traps fall into this miscellaneous category.

## Inshore Creel Survey

The primary objective of the inshore fisheries survey was to obtain the most accurate estimate of the total annual inshore fisheries harvest in order to monitor and manage the resource. Fishing activity has been monitored since the early 1960's when much of the early information was taken by DAWR conservation officers (law enforcement personnel). Monitoring changed over the years, as did fish identification. The early 1960's catch was identified by the Chamoru name of the fish. Problems with catch composition arose because one name could mean any wrasse species, parrotfish would be identified by color (blue, brown, white, and green), and rabbitfish would be identified by at least five names that described the fish by size. As taxonomic skill increased, the catch was reported in increasing detail.

Working closely with the U.S. National Marine Fisheries Service, the DAWR developed a program for analyzing the inshore fisheries. Since the installation, all the data collected has been analyzed by this program. In 1991, we modified and restructured our analysis to allow comparison of data from 1982 to the present. (Because of methodological changes, data prior to 1982 do not lend themselves to analyses.)

### Survey Methodology

Because much of the shoreline is inaccessible to most fishermen (i.e., military bases, clifflines), not all of Guam is surveyed. Data collection for the inshore fisheries expansion is conducted in an area representing 85% of the total fishing participation (verified from shoreline usage seen during aerial surveys). A two-part roving creel survey, effort (or participation) and catch, is performed for both day and night (begun in 1985) to provide sufficient data to allow for 90% confidence limits for the inshore analysis. Detailed methodology and analyses are described in Amesbury et al. (1991).

During an effort survey, a surveyor records all active fishing participation (time of day, location, number of people, number of gear units, fishing methods, reef zone fished, weather conditions, and surf conditions). Counts are made of fishermen and gear and are used to estimate effort in terms of person-hours (p-hr) and gear-hours (g-hr). The catch survey is of the roving fisherman-intercept type and requires as many interviews for as many fishing methods as possible. The survey variables collected include fishing method, number of fishermen, bait type, number of gear, mesh size, interview time, trip length, species caught, numbers of catch species, and individual weights and lengths. Catch data is used to estimate overall landings (kg), CPUE, and species composition.

The majority of the species caught are represented with this methodology. Species that recruit en masse, like mañahak (rabbitfish) or atulai, cannot be adequately represented in the current creel survey. Catch estimates of these species are obtained when the recruiting runs occur and are added to the survey expansion catch values to obtain the yearly inshore harvest.

### Finfish

Finfish are the primary harvest (usually >95%) of contemporary fishing methods. This harvest includes all sizes of reef fish, even the highly anticipated seasonal runs of juveniles. Deepwater and/or pelagic fish, normally harvested using offshore techniques, are occasionally caught using inshore methods. Over 100 species of finfish are harvested in the inshore fishery. The primary families include: Acanthuridae, Carangidae, Gerreidae, Holocentridae, Kyphosidae, Labridae, Lethrinidae, Lutjanidae, Mugilidae, Mullidae, Scaridae, and Siganidae. The top ten species caught in the inshore fishery, not including seasonal juveniles, are *Naso unicornis, Caranx melampygus, Siganus spinus, Mulloides flavolineatus, Lethrinus harak, Valamugil engeli, Kyphosus cinerascens, K. vaigiensis, Cheilinus fasciatus,* and *Gerres* sp. Ranking of these species changes as fishing pressure and gear use fluctuates.

The harvest of one of these key species, *Mulloides flavolineatus*, best describes what is occuring in the finfish fisheries. By 1991, the harvest declined by 90% over a 6-year period (from 33,896 to 3,417 kg). The 100–150 mm size class is targeted in the traditional fishery, which prevents many fish from reaching larger size classes and further impacts the reproductive potential of the population. The downward trend in overall harvest is characterized by the absence of larger females that represent the major portion of the spawning potential.

Many of the once economically important larger species, like the humphead parrotfish, *Bolbometopon muricatum*; wrasse, *Cheilinus undulatus*; groupers over 25 kg, and snappers are rarely seen in Guam's waters, much less reported on the inshore survey catch reports. Interest in the harvest of aquarium fish is on the rise, while the actual harvest appears to be declining. These fish may be less susceptible to overfishing because of their high turnover rate, but problems are beginning to surface with respect to the use of chemicals for fish collecting, habitat destruction, and unmonitored or illegal catches.

The harvest of recruiting juvenile fishes (Table 1) makes up Guam's traditional finfish fishery. It historically has been and still remains an important part of the nearshore reef fisheries. Seasonal juvenile harvest can range from a minor component of <1% (in 1982–83) to over 50% of the overall harvest (in 1991).

Two major components of the juvenile harvest are mañahak and atulai (Fig. 2). The local residents anxiously await the recruitment of both species to the nearshore reef waters. Even though the yearly run of mañahak does not always occur, fishermen will gather at the shoreline during the first few days of the last quarter lunar phase of the expected recruitment period. The mañahak recruit onto the flat area of the reef in aggregations or "balls", as they undergo morphological development from planktivorous to herbivorous fish (Kami and Ikehara, 1976). The largest, as well as the most economically valuable, catch of mañahak is prior to the complete coloration and dietary change (the first 1–2 days on the reef). Harvesting of mañahak is conducted with all nets using a $^1/_4$–$^1/_2$ inch stretch mesh size. Atulai usually begin their seasonal runs into inshore waters by the age of 4 months (Amesbury et al., 1986). The atulai are harvested with surround nets, cast nets, and by hook and line and usually represent the majority of the seasonal harvest.

The recruitment of other juveniles, like i'e' (jacks), ti'ao (goatfish), en masse and aguas (mullet), do not occur like the mañahak or atulai, but they are still heavily fished. The recruitment periods for these juvenile fishes often overlap and peak harvests are seen every 3–4 years. The harvest of these juveniles is primarily by net fishing

**Table 1.—Seasonal juvenile fishes targeted in Guam's traditional finfish fishery. Chamoru names are after Kerr (1990).**

| (English Name)<br>Chamoru name | Family and species targeted |
|---|---|
| Aguas (mullet) | Mugilidae |
| Atulai (bigeye scad, mackerel) | Carangidae; *Selar crumenopthalmus* |
| Achemsom[1] (fusilier) | Caesionidae |
| I'e' (jacks) | Carangidae; primarily *Caranx melampygus* |
| Mañahak (rabbitfish) | Siganidae; *Siganus spinus*, *S. argenteus* |
| Ti'ao (goatfish) | Mullidae; *Mulloides flavolineatus* |

[1] Many local fishermen use this name to incorrectly identify juvenile fusiliers when they recruit en masse. Achemsom actually means small rainbow runner (Carangidae; primarily *Elegatis bipinnulatus*).

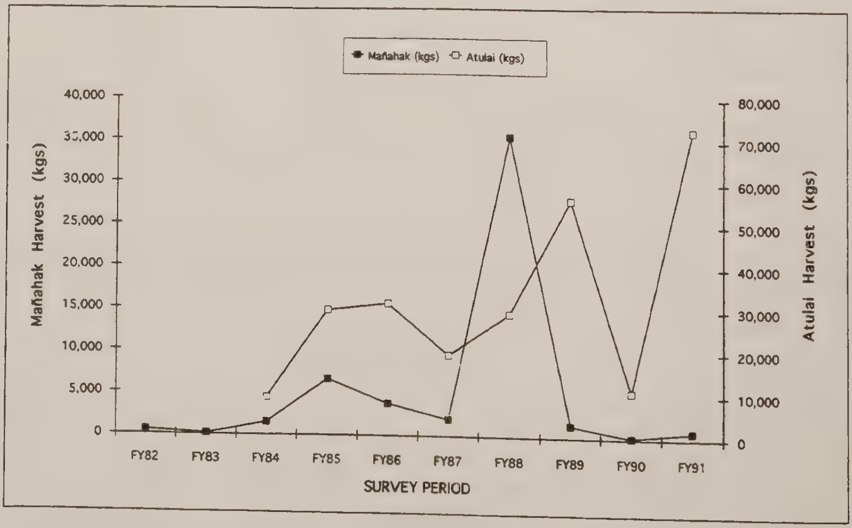

Figure 2.—Estimated harvest from 1982 through 1991 of two of Guam's seasonal juveniles (mañahak = young rabbitfish, primarily *Siganus spinus*; atulai = young mackerel, *Selar crumenopthalmus;* FY = 12-month fiscal year). Names are after Kerr (1990).

(using 1/4–1/2 inch stretch mesh size), except the i'e' which are often harvested by hook and line.

### Nonfinfish

Until recently, the funding constrained the DAWR to work on finfishes only; therefore, information on nonfinfish is limited to catch statistics for methods that also target finfish. Since harvesting of invertebrates is one of the less frequent and easily missed activities (i.e., virtually all lobsters are taken by spearfishing), our nonfinfish harvest is probably underestimated. For a few of the species most often collected, the true annual catch is probably only a few metric tons at most.

The coral reef is Guam's single most valuable resource, and, over the years, coral has been harvested for ornamental and commercial use. The most common corals harvested commercially in the past included *Acropora*, *Antipathes*, *Fungia*, *Heliopora,* and *Tubipora* sp. (Hedlund, 1977). Coral (dead or live) is no longer legally collected without a permit (now issued for educational or research purposes only), and the regulation is strictly enforced.

Two species of green algae (*Caulerpa racemosa* and *Codium* sp.), two species of red algae (*Gracilaria edulis* and *Asperagopsis* sp.) and one species of brown algae (*Sargassum polycystum*) are commonly harvested (Hedlund, 1977). The green algae or seaweed is seasonal (usually January through May) and when collected, is often sold at local markets. Sargassum and *Enteromorpha* sp. are also collected as bait for rod and reel fishing for herbivores[4].

Many molluscan species have been and are still harvested on Guam. About 15 bivalve species (3 of which are tridacnid clams) have been harvested on Guam (Stojkovich and Smith, 1978). Other shelled mollusks collected include *Trochus* sp. (topshell or aliling), chitons, conchs, nerites, and strombids (Smith, 1986). A few of these mollusks (plus some not mentioned) are collected for ornamental use. The octopus is the most sought after unshelled mollusk; squid and cuttlefish form part of the incidental catch. Of all these, only *Trochus* has a fisheries potential and is currently regulated with size restrictions and is strictly monitored.

Crustaceans make up a major portion of the nonfinfish catch. About nine species of crab are hunted, including land and marine crabs. *Carpilus maculatus* (7–11 crab) and *Etisus splendens* are primarily targeted, whereas *Calappa hepatica* and rarely *C. calappa* (box crabs) are taken as incidental catch during net fishing, spearfishing, or gleaning. Two species of land crabs (*Cardisoma carnifex* and *Birgus latro*) are also highly prized, but are not monitored on the inshore fisheries surveys. Lobster catches are highly prized. The following species are identified in Guam's catches: Palinuridae (*Panulirus longipes*, *P. ornatus*, *P. pencillatus*, *P. versicolor*), Homaridae, and Scyllaridae. The spiny lobster, primarily *P. pencillatus* and the slipper lobster, *Scyllarides squamosus*, are the two main components of the inshore lobster catch and are harvested by spearfishing and "other" techniques (i.e., gleaning). Mantis shrimp, another crustacean, is often mistaken for lobster by some fishermen. It is harvested by hooks and gaffs, shrimp traps, and through incidental catches.

Smith (1986) stated that other invertebrates harvested have included two species of sea urchins (*Tripneustes gratilla* and *Echinometra mathaei*), two species of sea cucumbers (*Stichopus horrens* and *Holothuria atra*) and a freshwater shrimp (*Macrobrachium* sp.). The sea urchin *T. gratilla* has been harvested for ripe gonads. The harvest of sea cucumbers is sporadic (*H. atra* is the most common species harvested). Present harvest is less than that reported in the late 1800's, when catches of 2–3 tons were documented (Amesbury et al., 1986).

Five species of sea turtles have been identified in Guam's waters[5]. Harvest of sea turtles on Guam was prominent prior to World War II and occurred legally until 1976. Inshore catch reports for 1967–68 noted landings of over 80 turtles in 18 months, the largest individuals weighing an estimated 450 pounds. It is currently difficult to determine the extent of the actual catch because of the illegal nature of this activity. Examples of significant poaching activities were seen during a 2-week period in 1990–91, when an estimated 20 turtles (in two separate incidents) were poached.

### Catch and Effort Estimates

Overall catch values for 1982–91 for all fish caught (finfish, nonfinfish, and seasonals) for both day and night are shown in Figure 3. In 1990, the participation declined to less than 50% (42,294 fishermen) of the 1984 high (107,391 fishermen). Similar trends for effort and catch are seen (Fig. 3) where the highs occurred in 1984, but lows occurred in 1989 and 1990. Effort and participation increased in 1991 and are attributed to an excellent year for seasonal juvenile harvest. If harvest estimates for atulai and mañahak (Fig. 2) were removed from the catch values, the overall harvest falls between 1989 and 1990 estimates. The 3–4 year pulse of other juveniles (i'e', aguas, and ti'ao) was also observed in 1991 and falsely elevated the survey estimates (number of participants, gear, catch, etc.). If the juvenile harvest values were removed from all years, the 1991 harvest estimate would still be smaller than any previous year.

### Day Fishing Estimates

Day harvest and effort values for means for reef fisheries during 1982–91 are shown in Figure 4. A 60% decline in the number of fishermen occurred in 1990 (30,396) from a high in 1984 (97,603). Similar trends for inshore finfish are seen for both effort and catch (Fig. 4) where highs occurred in 1984. Catch follows effort until 1988 when harvest continues to drop while the effort increases. Nonfinfish effort declined over 90% by 1989 (2,759g-hr) from a high in 1982 (28,613 g-hr). Harvest of nonfinfish, though underestimated, declined from 29,499 kg in 1982 to 1,289 kg in 1990. Both finfish and nonfinfish show declines in effort and harvest estimates for 1988–91 as compared with the 1982-87 period.

## Night Fishing Estimates

During the night surveys from 1985 through 1991, effort reached a high for finfish in 1987 (58,893 g-hr) and declined more than 50% to a low in 1990 (25,181 g-hr). Night harvest of finfish rose to a high of 23,538 kg in 1988 before declining to less than 50% in 1991 (10,285 kg). Nonfinfish showed little change in effort until the drop in 1989–90 (from >2,000 to 340 g-hr). The overall night harvest was composed of nonfinfish harvest that ranged from 3.2% (361 kg) in 1989 to 23% (4,684 kg) in 1986.

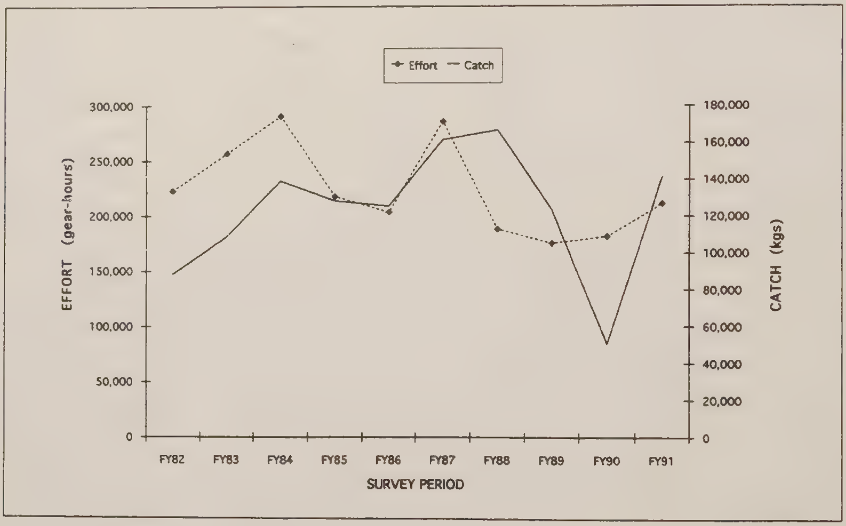

Figure 3.—Estimated effort and harvest of Guam's nearshore reef fisheries from 1982 through 1991 (catch = harvest of all finfish and nonfinfish for both day and night, FY = 12-month fiscal year).

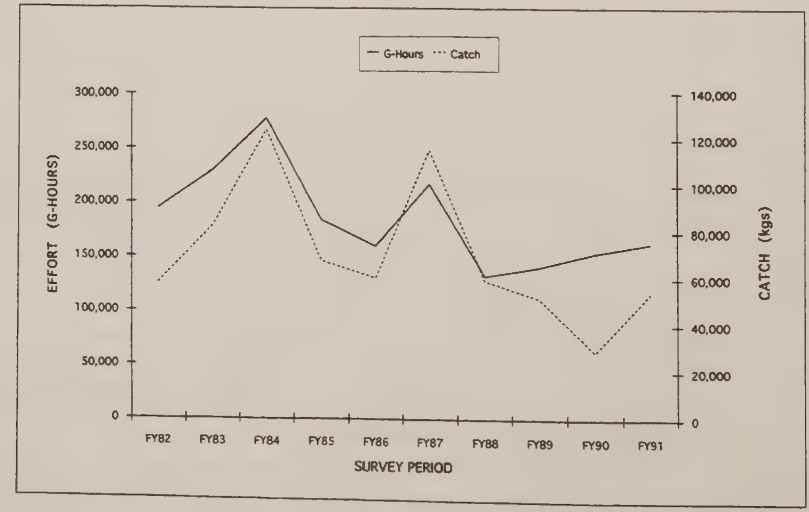

Figure 4.—Estimated effort catch of Guam's inshore fisheries for the daytime from 1982 through 1991 (catch = total harvest of finfish without mañahak or atulai harvest, FY = 12-month fiscal year).

## Gear Usage and CPUE

The most popular fishing methods for day and night are seen in Figures 5 and 6, respectively. Hook and line is the most popular method for both day and night, but consistently has one of the lowest CPUE's (catch per unit of effort) ranging from 0.05 to 0.36 for both day and night. The second and third most popular methods for day fishing are cast and gill net. During 1982–84, "other" displaced gill net from the top three. After 1985, most of the participation can be seen with the top three methods (hook and line, cast net, and gill net).

Figure 6 shows the most popular night fishing methods. Spearfishing with snorkel gear ranks second, more often than gill net, drag net, or "other"methods. Except in 1985, when "other" displaces gill net from its third ranking, gill net fishing has increased in popularity where it ranked second for 1986–91.

Many gear use fluctuations are due to the popularity of methods with high CPUE's. The highest day CPUE's (usually about 2.0–4.7) are most often seen with net fishing (mainly drag net, surround net, and gill net) followed by slightly lower CPUE's for spearfishing with scuba and "other". Night CPUE's fluctuate more than day CPUE's and are highest for spearfishing, drag netting, and gill netting. Much of the CPUE fluctuations, especially with net fishing methods like cast, drag, and gill net, can be attributed to the seasonal aspect of the fisheries with respect to traditional fish harvests.

## Research

The DAWR has been involved in many aspects of research. For many years, aquaculture potential for freshwater finfish was investigated. Currently, aquaculture research is still conducted (marine finfish and invertebrates) and involves another government agency, private companies, and the University of Guam. Most recently, DAWR began a study of the feasibility of restocking the giant clam *Tridacna derasa*. Studies on the biology and life histories of some recreationally important fishes began in 1984. To date, *Siganus spinus* and *Mulloides flavolineatus* biological profiles have been completed, with *Lethrinus harak* in progress. These biological investigations have been aided by the graduate program at the University of Guam where students investigate important species like *Acanthurus triostegus*, *A. lineatus*, and *Naso literatus* (Molina, 1983; Davis, 1985). Even with the research being done by local and visiting scientists, there is still an enormous amount of information lacking on Guam's fishes.

Work toward identifying the many fish species in Guam's waters has occurred (Kami et al., 1968; Kami, 1971, 1975; Myers and Shepard, 1980; Shepard and Myers, 1981; Amesbury and Myers, 1982; Myers, 1988, 1989). This documentation continues as new species are recorded. The species composition of the fishery on Guam has been made possible by the various check-lists of the fishes in Guam's waters. Aerial surveys are periodically performed to monitor inshore fishing activity in nonsurveyed areas of Guam. Incidental information acquired includes offshore fishing information and turtle abundances[5].

Future investigations are planned for other recreationally important reef species to make sound management suggestions (size, bag limits, seasonal closures). Otolith work has been initiated through the University of Guam.

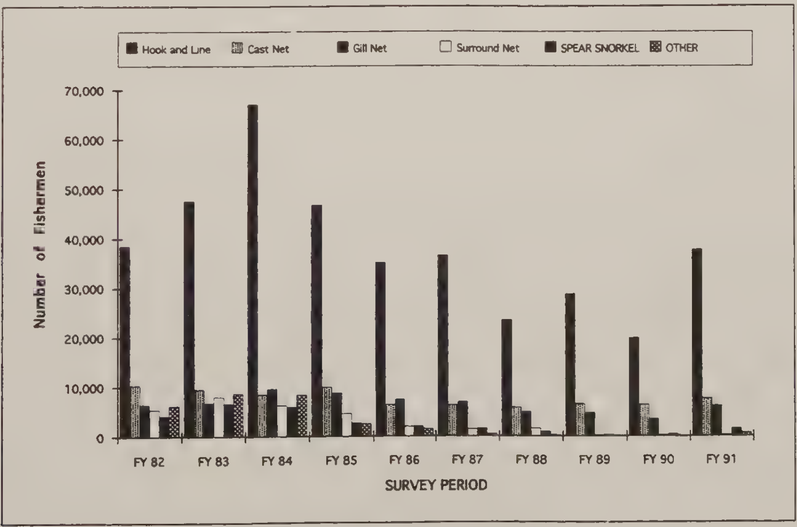

Figure 5.—The most popular fishing methods in Guam's inshore fisheries for the day from 1982 through 1991 (number of fishermen = number of people using specific method; FY = 12-month fiscal year.)

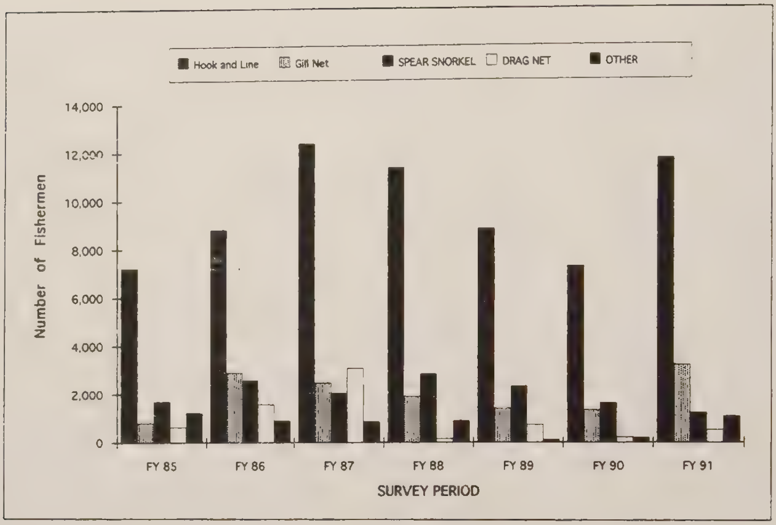

Figure 6.—The most popular fishing methods in Guam's inshore fisheries for the night from 1985 through 1991 (number of fishermen = number of people using specific method, FY = 12-month year).

Analyses of the stocks and future fishing potential is continuing through the modifications in existing expansion methodology and creel survey information[6].

### Management Concerns

As the human population grows, modern fishing techniques improve, and fish stocks decline, the need for the management of Guam's tropical coral-reef fisheries increases in order to protect the reef habitat from overfishing as well as from pollution and destruction. The effects of pollution are seen as a result of development and population growth. Much of Guam's southwestern coral reefs are covered with silt from freshwater runoff. Because water quality is extremely important to viable coral reefs (and fish populations), strict standards for development, land clearing, and chemical use should be initiated and enforced. Other major causes of reef destruction includes the use of explosives and poisoning (chlorine bleach and *Barringtonia* root) as fishing methods. Both types of fishing are illegal, but through an education program (with respect to problems associated with destructive fishing practices) and strict enforcement, these have been declining.

Besides pollution and destruction of the reef habitat, it is imperative that a comprehensive management program be established for Guam's fisheries. There are enough indicators that fishing pressure on Guam's inshore resources has reached the point of overexploitation of many of the key species. The proportion of juvenile fish in fisheries landings is increasing rapidly. "Growth overharvesting" has been occurring, and the overall yield has declined as a larger and larger portion of smaller fish are harvested. It is very likely that "recruitment overharvesting," where the reproduction and recruitment of the stocks show a decline, is currently occuring in some of the recreationally important species.

### Management Recommendations

Currently, there are several seasonal, area, gear, and size restrictions and bag limits on Guamanian fisheries. These pertain mostly to nonfinfish such as the spiny lobsters, tridacnid clams, *Trochus,* and crabs. Gear restrictions are the only regulations pertaining to finfish harvest. Minimum mesh sizes of 1 1/2 inches on gill nets (except for traditional or juvenile harvest) and hook restrictions for atulai (no snagging) are the principal restrictions. Other gear restrictions include length and time limits for gill net fishing and the prohibited use of fish weirs.

New regulations are currently awaiting approval with one of the most promising avenues being the development of marine conservation area(s). These should be established to provide a refuge for recreationally important fish so they can grow, mature, and reproduce to increase stock health and recruitment. Besides the ability of an area closure to protect fish from harvest, there are many other benefits that make this an increasingly popular form of management and conservation. The closure limits the catches on adjacent reefs without closing down the entire fishery and provides areas where user conflicts are minimized.

Gear restrictions should be implemented and enforced. Because no other method for the seasonal harvest (with mesh sizes as small as 1/4 inch) is as dangerous to the entire fishery as the nonselective method of gillnet fishing, this method should be heavily regulated. The minimum mesh size for gill nets should be 3 inches, maximum length of time used should be decreased, and it should be required that all nets be manned at all times. The use of gill nets for juvenile fish harvest should be eliminated (except atulai where a $1^{1}/_{2}$-inch minimum mesh size should be kept). Other nets, like cast nets and drag nets could still be used for juvenile harvest without the damage to the fish stocks that gill netting may cause. All commercial fishing for seasonal juveniles using nets with mesh sizes less than $1^{1}/_{2}$ inches should be prohibited. Because of the environmental damage that sometimes occurs with drag nets, the use of this method should be restricted to specific areas where minimal destruction of habitat would occur. Spearfishing with scuba gear should be prohibited because the few remaining large fish of overexploited species are being targeted.

---

[6] Hensley, R. A., and T. S. Sherwood. Unpubl. data. Texas Parks and Wildlife Department, 1231 Agnes St., Corpus Christi, TX 78401.

Appropriate management strategies are difficult to develop when dealing with multispecies, multigear fisheries. Management is further impeded by the desire to hold on to traditional fishing activities which involve the harvest of juvenile fishes. To ensure that future generations enjoy the traditional harvest of juveniles as well as other fishes, strict management regulations must be implemented. Of course, the ability of any management approach also depends on ensuring a healthy and clean reef environment to provide adequate habitat and optimal reproduction.

## Market Description

The DAWR has been keeping track of the catch sold by offshore recreational fishermen (Myers, 1993) and has recently begun to document other catches, including nearshore reef fishes. The market for nearshore reef fish has increased on Guam, especially with the diverse cultures that eat fish as a primary source of protein. With the influx of new people and the desire for local fresh fish, the market continues to expand. Because the prices are high, with the average price of \$3–4/pound for whole reef fish, the financial benefit for fishermen using a high CPUE method (gill net, surround net, drag net) is enormous. Many of the net fishermen encountered on the inshore survey are no longer subsistence fishermen but are commercial fishermen.

Reef fish imports from Belau and the Federated States of Micronesia are increasing. It is difficult to determine the amount of fish imported because few restrictions are placed on importation. Further difficulties occur in monitoring sales of local and imported fish because of the manner in which they are sold. Many fishermen sell their catch on the roadside, while others sell to small local stores or the large supermarkets. Continued monitoring is necessary to obtain more knowledge of the commercial aspect of the inshore fisheries.

## The Future

The outlook for Guam's inshore fisheries, given the current catch information, is poor. If management strategies are not incorporated soon, the remaining fishery may continue to decline to the point of poor productivity. The need for fishery imports will continue to increase as local stocks decline. This lower abundance and availability of Guam's fishery resources could cause higher fishing pressure on neighboring islands.

The ability to manage Guam's fisheries is limited by local politics. In an effort to protect the traditional fishing practices of the Chamorus, legislation has been passed without any apparent foresight of impact on other aspects of the fishery. Interpretation of the term "traditional" has allowed fishing practices acquired since WWII (i.e., gill netting) to continue with little to no regulation. If allowed to continue, the change from subsistence fishing to "traditional" commercial fishing will continue to strain Guam's fishery resources.

The picture is not as bleak as it may appear, however, because many Guamanians are beginning to become environmentally aware. This is demonstrated by the increasingly high number of informants regarding illegal fishing practices (turtle poaching, coral harvesting, gill net abandonment, etc.). The DAWR continues to address the aspect of educating tourists (over 740,000 in 1990) and temporary workers from foreign lands about local regulations. As Guam's population and a need for housing increases, illustrated by the recent closure of the U.S. military bases in the Philippines and the subsequent transfer of 2,000 families to Guam, we see greater threats to the reef resources than we have now. With the help of the general population and the passage of rigid regulations, there is still hope for the fishery to rebound. However, it is highly unlikely for future harvests to reach pre-1987 totals.

## Acknowledgments

We would like to thank M. J. McCoid and G. W. Davis for their critical review of this manuscript and all the data collectors that were involved in this project over the years. We also thank G. Boehlert and two anonymous reviewers for their comments. This project was funded by the Federal Aid in Sport Fish Restoration Act (Guam Fisheries Investigation-Project FW-2R-22).

# Dispersion and abundance of Antarctic krill in the vicinity of Elephant Island in the 1992 austral summer

**Roger P. Hewitt**[1], **David A. Demer**[2,*]

[1]Southwest Fisheries Science Center, La Jolla, California 92038, USA
[2]Scripps Institution of Oceanography, La Jolla, California 92093, USA

ABSTRACT: Antarctic krill *Euphausia superba* distribution and abundance were estimated from 4 acoustic surveys conducted in the vicinity of Elephant Island, Antarctica, from mid-January to mid-March 1992. The first and last surveys covered a 105 by 105 n mile study area centered on Elephant Island; the second and third surveys covered a 60 by 35 n mile area immediately north of Elephant Island. During the first survey, krill were distributed in a wide band extending along the north side of Elephant Island and wrapping around the western end; biomass was estimated to be 2.2 million metric tons (t). During the second survey, the highest densities of krill were over the shelf extending to the northwest from Elephant Island and including the Seal Island archipelago; high densities of krill also extended off the shelf from the northeast end of Elephant Island into deeper water. Biomass in the smaller survey area was estimated to be 0.7 million t. Three weeks later, high krill densities were still apparent in the vicinity of Seal Island, but the area of high density previously mapped off the northeast end of Elephant Island had diminished considerably; biomass was estimated to be 0.4 million t. During the final survey, conducted 6 wk after the first survey, krill were mapped in reduced densities primarily to the west of Elephant Island; biomass over the larger survey area had declined to 1.1 million t.

## INTRODUCTION

Antarctic krill *Euphausia superba* is a key component in the pelagic marine ecosystem of the Southern Ocean (Laws 1985). As much as 300 million metric tons (t) of krill may be consumed annually by 30 million pinnipeds, 50 million sea birds and 300 000 baleen whales (Miller & Hampton 1989). It is also the target of an international fishery (ca 400 000 t annually). Although the harvest is less than 1% of the annual krill production, catches tend to be localized near penguin and fur seal breeding colonies (Agnew in press). The effects of fishing, however, on the reproductive success of land-breeding krill predators has yet to be demonstrated. To do so, it will first be necessary to document the response of predator populations to features of the offshore prey field, and then to determine the effects of fishing on the distribution of prey.

In response to international concern regarding unregulated development of fisheries in the Southern Ocean, the Convention of the Conservation of Antarctic Marine Living Resources (CCAMLR) was established as part of the Antarctic treaty system in 1982. A principal tenet of the convention is that the harvest of living resources shall be managed with the goal of preserving species diversity and stability of the entire marine ecosystem. Through its Scientific Committee, CCAMLR has encouraged member nations to establish long-term programs to monitor foraging behavior and reproductive success of selected krill predators (SC-CAMLR-IV 1985, SC-CAMLR-V 1986, Croxall et al. 1988, Croxall 1989). More recently the Scientific Committee called for descriptions of the prey distribution and abundance in the vicinity of predator monitoring sites and adopted a series of general principles to be used in the design of krill surveys (SC-CAMLR-X 1991). It was recommended that: (1) acoustic data be collected along a series of regularly spaced parallel transects; (2) these data be used to map the distribution

of krill in the vicinity of a predator monitoring site and estimate their abundance; and (3) more focused surveys, consisting of randomly or regularly spaced parallel transects, be conducted in areas of highest krill density.

A seasonal predator monitoring site has been maintained at Seal Island, off the northwest coast of Elephant Island, Antarctica, since the austral summer of 1986/1987 (Bengtson et al. 1991, Boveng et al. 1991, Croll et al. 1991). An annual series of complementary shipboard observations, including acoustic surveys of zooplankton distribution and abundance, has been conducted in the waters surrounding Elephant Island (Anon. 1990, Rosenberg & Hewitt 1991, 1992). The acoustic surveys presented in this report are the latest in the series.

Results from previous surveys suggest that the distribution, abundance and demography of krill in the Elephant Island area varies considerably both within and between years (Mathisen & Macaulay 1983, Kalinowski 1984, Macaulay et al. 1984, Kalinowski et al. 1985, Klindt 1986, Nast 1986, Siegel 1986b, Brinton et al. 1987), and that these changes are due to immigration and emigration of krill rather than local population effects (Priddle 1988, Sahrhage et al. 1988). Spatial separation of adults, sub-adults and juveniles suggests that offshore waters west of the Antarctic Peninsula are krill spawning areas and that the neritic zone may be used as nursery grounds (Fevolden & George 1984, Quetin & Ross 1984, Siegel 1986a). Siegel (1988) proposed that adult krill migrate from the southwest (Bellingshausen Sea) into offshore waters during the summer, that sub-adults and juveniles drift to the northeast with the prevailing coastal current, and that the direction of these movements is reversed the autumn. Makaorov et al. (1988) and Nast et al. (1988) noted that Elephant Island lies in the path of a major outlet from the Weddell Sea, and that variations in the position of the Weddell-Scotia Confluence (WSC) may account for the variation in the numbers of krill accumulating in the Elephant Island area from the northern Weddell Sea. Stein (1986) described seasonal variations and meanders in the position of the WSC, which is apparent as a persistent hydrographic front north of Elephant Island. The meanders and eddies in the current flow along the front may be a factor favoring the accumulation of krill in the Elephant Island area, regardless of their origin (Everson 1984, Witek et al. 1988).

Two objectives of our field research program are to: (1) relate the response of krill predators to changes in the availability of their prey; and (2) relate these changes to biotic and abiotic aspects of the pelagic habitat. As such, there is interest in both the spatial patterns of krill distribution as well as their abundance. The analyses presented here were conducted to reveal features of krill distribution that persisted over relatively large scales (tens of km, and several days). Analyses of these data on finer scales will be reported elsewhere.

## METHODS

Echo integration methods were used to map the distribution of krill and estimate its abundance in the vicinity of Elephant Island. Four surveys were conducted between 19 January and 11 March 1992 (Fig. 1a, b).

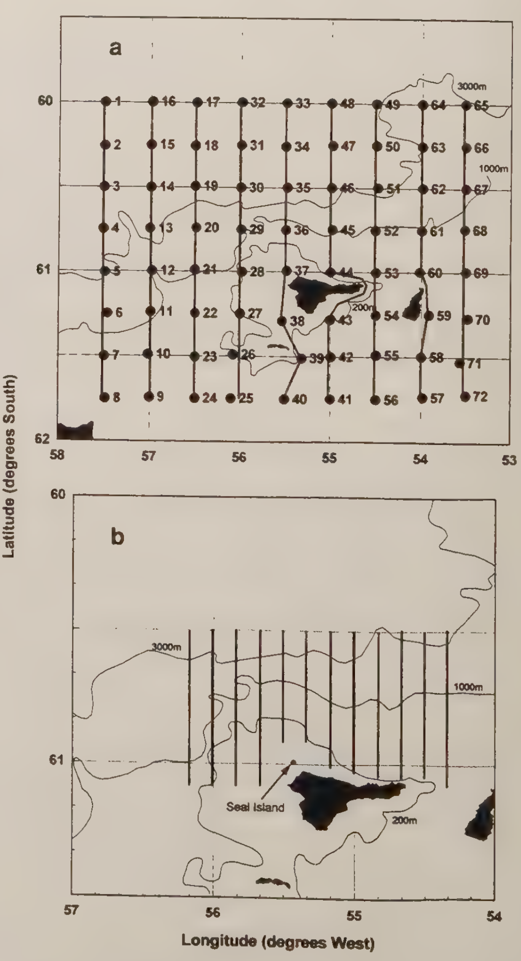

Fig. 1. (a) Station pattern and acoustic transects for Surveys A and D. (b) Acoustic transects for Surveys B and C

Surveys A and D were designed to describe meso-scale (tens to hundreds of km) features of water mass structure, phytoplankton biomass and productivity, and zooplankton constituents (including krill) in the area around Elephant Island. Surveys B and C were designed to map the micro-scale (one to tens of km) features of the distribution, density and abundance of krill immediately north of Elephant Island, within the foraging range of krill predators breeding at Seal Island.

Acoustic data were collected with a Simrad EK500 echo sounder (Bodholt et al. 1989) configured with a 120 kHz split-beam transducer. The transducer was deployed on a dead-weight towed body positioned 7 m below the water surface, and communicated with the echo sounder via 50 m of armored towing cable, a set of slip rings on the towing winch, and 75 m of shielded deck cable. The entire system (echo sounder, cables and winch) was calibrated before and after the cruise using standard sphere methods (Johannesson & Mitson 1983) in a 3 m diameter by 10 m deep tank filled with seawater chilled to 0.5 °C; calibration drift was less than 1.2 dB (Demer & Hewitt in press).

Echo power levels for each ping were sampled approximately every 3 cm (25 kHz sampling rate) and adjustments were made for spherical spreading and absorption losses. This data set was averaged every 0.5 m over depths ranging from 10 to 250 m, and the resulting set of mean volume backscattering strength measurements ($s_V$) was passed to a computer for further processing and archiving.

Echograms were generated from the subsampled data set and interpreted. The threshold volume backscattering strength was set at −81 dB (equivalent to approximately 0.1 krill $m^{-3}$), and portions of the echogram were attributed to echoes from krill and non-krill (bottom return, system noise, other scatterers). For the purpose of generating distribution maps and biomass estimates, volume backscattering strength attributed to krill was integrated over 10 to 250 m depth range (or 1 m above the bottom, if shallower than 250 m) and averaged over 1 n mile intervals. Ship's position was also recorded every 10 s and time-keyed to the acoustic data set. Version 2.6 of the 'Bergen Integrator' software, co-developed by the Bergen Institute of Marine Research, the Christian Michelsen Institute, and Simrad (Knudsen 1990, Foote et al. 1991), was used as an aid in interpreting the echograms and archiving the results.

Mean backscattering area per square n mile of sea surface ($s_A$) for every 1 n mile of survey transect [$m^2$(n mile)$^2$] was thus calculated by the Bergen Integrator software as:

$$s_A = 4\pi r_0^2 1852^2 \int_{z=10}^{z=250} s_V \, dz \qquad (1)$$

where $s_V = 0$ if $10 \log(s_V) \leq -81$ dB; $z$ = depth; and $r_0$ = 1 m is the reference range for backscattering strength.

By assuming that measurements of $s_V$ represent the linear sum of echoes from individual animals within the sample volume (MacLennan & Simmonds 1992), the numerical density of krill (number per unit area of sea surface) can be estimated by dividing $s_A$ by the backscattering cross-sectional area ($\sigma$, $m^2$) of a single krill. Biomass density of krill ($\rho$, g $m^{-2}$) can be estimated by multiplying the numerical density by the weight of a single krill.

Both the backscattering cross-sectional area and the weight of krill are non-linear functions of body length. We used the definition of krill target strength (*TS*, dB) as a function of standard length ($l$) as proposed by Greene et al. (1991) and adopted by the CCAMLR Working Group on Krill (SC-CAMLR-X 1991) (see also 'Discussion'):

$$TS = -127.45 + 34.85 \log_{10}(l) \qquad (2)$$

where $l$ = standard length of krill (mm). The corresponding backscattering cross-sectional area of krill ($\sigma$) is:

$$\sigma = 4\pi r_0^2 10^{-12.745} l^{3.485} \qquad (3)$$

The relationship of krill wet wt ($w$, mg) as a function of standard length was taken from Siegel (1986a) for individuals caught in March:

$$w = 0.00193\, l^{3.325} \qquad (4)$$

Thus:

$$\rho = s_A \frac{w}{\sigma} = 0.249\, l^{-0.16} s_A \qquad (5)$$

Krill were sampled directly with a 6 ft (ca 1.8 m) Isaacs-Kidd midwater trawl (IKMT, Devereux 1953), outfitted with a net made of 505 µm mesh nytex, and fished obliquely from approximately 170 m depth to the surface (Loeb & Siegel in press). Net tows were made at regularly-spaced stations on Surveys A and D (Fig. 1a) without regard to time of day; no net tows were conducted during Surveys B and C. The frequency distribution of krill standard length was used to calculate $\rho$ as follows:

$$\rho = 0.249 \sum_{i=1}^{n} f_i (l_i)^{-0.16} s_A \qquad (6)$$

where $f_i$ = the relative frequency of krill of standard length $l_i$, such that $\sum_{i=1}^{n} f_i = 1$, where $i$ refers to the $i$th length class and $n$ is the number of length classes.

A composite frequency distribution of krill standard length was calculated from all net tows conducted during Survey A and used to estimate densities on Surveys A and B; similarly a composite frequency distribution was calculated from all net tows conducted during Survey D and used to estimate densities on Surveys C and D. The resulting data sets, indexed by time and ship's position, were gridded and contoured for each of the 4 surveys.

Following the method proposed by Hampton (1987) and Jolly & Hampton (1990), each transect was considered a single sample of biomass density. The entire survey area was treated as a single stratum. Mean biomass density ($\bar{\rho}$) was calculated as a weighted mean:

$$\bar{\rho} = \frac{\sum_{i=1}^{N} \bar{\rho}_i (n_i)}{\sum_{i=1}^{N} n_i} \tag{7}$$

where $\bar{\rho}_i$ = mean density on the *i*th transect; $n_i$ = no. of 1 n mile averaging-intervals on the *i*th transect; and N = no. of transects. Following Jolly & Hampton (1990) and Simmonds et al. (1991), variance of $\bar{\rho}$ was estimated as:

$$\bar{\rho} = \frac{N}{N-1} \frac{\sum_{i=1}^{N} (\bar{\rho}_i - \bar{\rho})^2 n_i^2}{\left(\sum_{i=1}^{N} n_i\right)^2} \tag{8}$$

Biomass was estimated as:

$$B = A(\bar{\rho}) \tag{9}$$

where $A$ = total survey area (m$^2$). Variance of the biomass estimate was calculated as:

$$\text{var}(B) = A^2 \text{var}(\bar{\rho}) \tag{10}$$

and the coefficient of variation as:

$$\text{CV} = \frac{\sqrt{\text{var}(B)}}{B} \tag{11}$$

The above expression only reflects the sampling variance (Simmonds et al. 1991). Other potential sources of errors and biases are outlined in the 'Discussion'.

## RESULTS

In late January, krill were distributed in a broad band which extended across the north side of Elephant Island and wrapped around its western end (Survey A, Fig. 2). During a higher resolution survey, conducted during the first week in February, highest krill densities were mapped over the shelf extending to the northwest from Elephant Island and including the Seal Island archipelago. High densities of krill also extended off the shelf from the northeast end of Elephant Island into deeper water (Survey B, Fig. 3).

A similar survey was conducted 3 wk later during the last week in February. Although high krill densities were still apparent in the vicinity of Seal Island, the area of high density previously mapped off the northeast end of Elephant Island had diminished considerably (Survey C, Fig. 4). A final survey, similar in areal coverage and sampling intensity to the first survey, was conducted during the first 10 d of March, 6 wk after Survey A. Both the extent and density of krill were greatly reduced; areas of highest densities were mapped to the west of Elephant Island (Survey D, Fig. 5).

The frequency distribution of krill standard length was bimodal throughout the study period (Fig. 6). Both

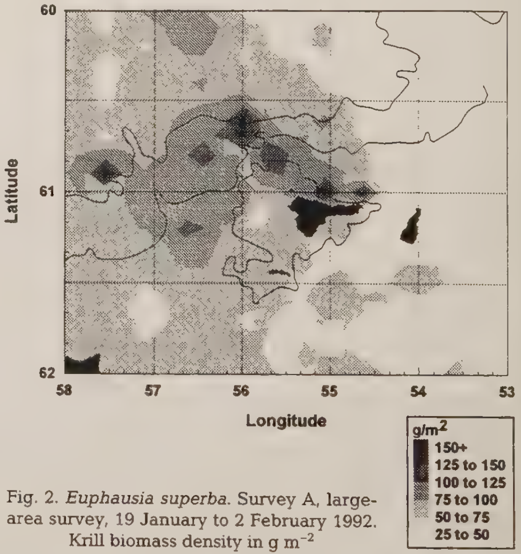

Fig. 2. *Euphausia superba*. Survey A, large-area survey, 19 January to 2 February 1992. Krill biomass density in g m$^{-2}$

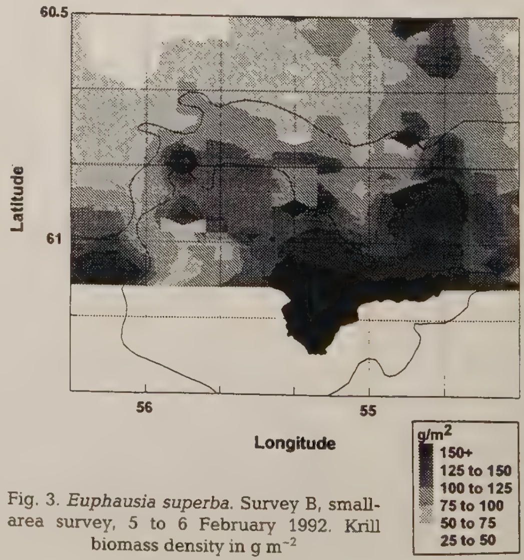

Fig. 3. *Euphausia superba*. Survey B, small-area survey, 5 to 6 February 1992. Krill biomass density in g m$^{-2}$

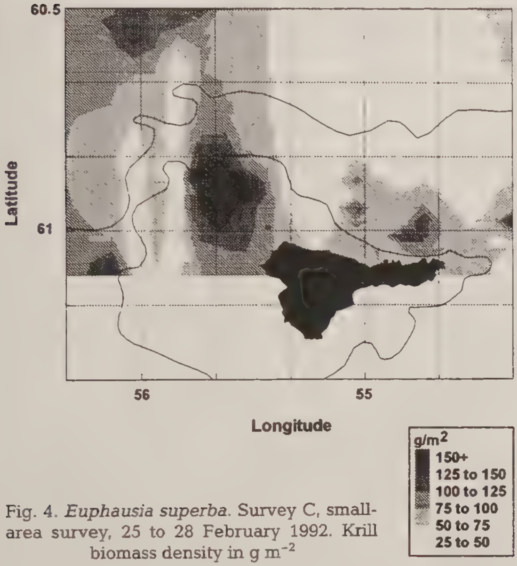

Fig. 4. *Euphausia superba*. Survey C, small-area survey, 25 to 28 February 1992. Krill biomass density in g $m^{-2}$

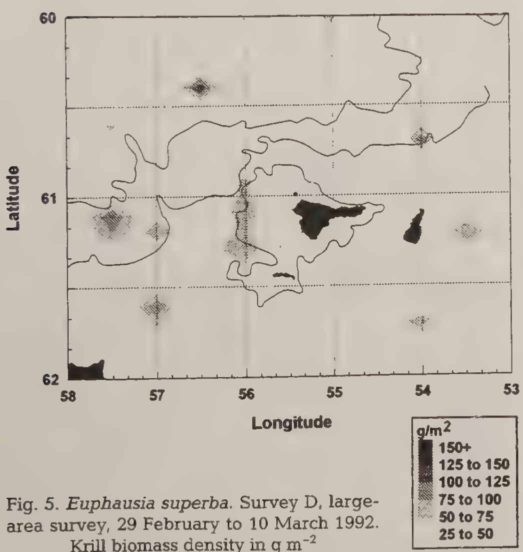

Fig. 5. *Euphausia superba*. Survey D, large-area survey, 29 February to 10 March 1992. Krill biomass density in g $m^{-2}$

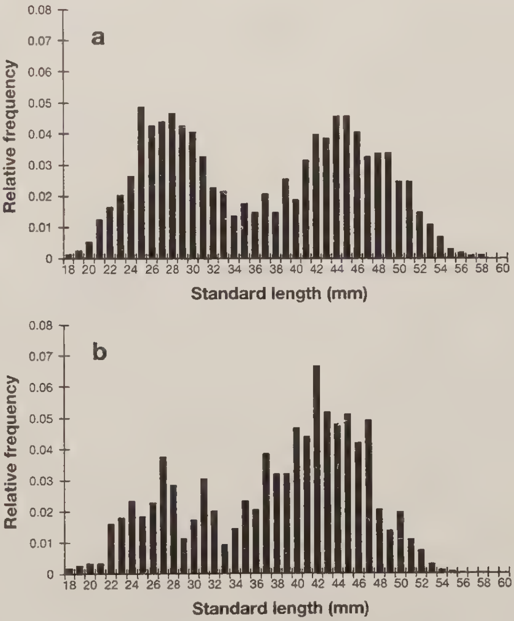

Fig. 6. *Euphausia superba*. Frequency distributions of krill standard length collected during (a) Survey A and (b) Survey B. From Loeb & Siegel (in press)

reproductively mature and immature adult krill contributed to the mode at 44 to 45 mm; juvenile krill constituted the mode at approximately 28 mm (Loeb & Siegel in press). Relative to Survey A, greater proportions of intermediate-sized krill and reduced proportions of smaller sizes were caught during Survey D. The size frequency obtained during Survey A was used to calculate krill densities on Surveys A and B, and the size frequency of krill obtained during Survey D was used to calculate krill densities on Surveys C and D.

During the first large-area survey (Survey A) krill abundance was estimated at 2.2 million t, CV = 16 %. Six weeks later (Survey D) krill abundance over the same area was estimated to be 1.1 million t, CV = 9 %. Estimated abundance during the first small-area survey (Survey B) was 0.7 million t, CV = 22 %, and during the second small-area survey (Survey C) it was 0.4 million t, CV = 23 % (Table 1).

## DISCUSSION

Several sources of error associated with the echo integration method can be identified. These include both random errors and systematic biases associated with the definition of individual krill target strength, estimating the size distribution of krill in the surveyed population, species identification, estimating the amount of undetected krill, assumption of a linear addition of echoes from individual krill in the sample volume, estimating system gain and absorption loss, and estimating survey sampling error.

Table 1. *Euphausia superba*. Foote et al. (1990) noted that abundance estimates of krill using acoustics were often much less than those obtained from estimates of predator demand. They suspected large errors associated with the definition of individual krill target strength, and ensonified live krill aggregations in a cage at 120 kHz. The mean single-animal target strength of 30 to 39 mm krill was inferred from the aggregation backscatter to range from −81 to −74 dB. Everson et al. (1990) noted that these values were considerably lower that those calculated from previously used equations relating target strength to the physical size of krill (BIOMASS 1986), and that the use of these equations resulted in gross underestimates of krill abundance. Until recently, a fluid sphere model was used to characterize the target strength of krill. Wiebe et al. (1990) ensonified several species of live, but tethered, zooplankton at 420 kHz and concluded that sound scatter from elongated animals is better described by a bent cylinder model (Stanton 1989), and that target strength is proportional to the volume of an animal rather than its cross-sectional area. Using these data, Greene et al. (1991) predicted krill target strength at several frequencies and over a range of body lengths. The Foote et al. (1990) data agreed with the Greene et al. (1991) prediction. Further corroboration was offered by Hewitt & Demer (1991) who reported a set of *in situ* target strength measurements using a 120 kHz split-beam transducer. For krill with an estimated mean length of 47.4 mm, the modal target strength was −69 dB, within 1 dB of the prediction by Greene et al. (1991). The CCAMLR Working Group on Krill reviewed these and several unpublished studies on krill target strength and concluded that 'a growing body of evidence suggests that the BIOMASS definition of target strength as a function of body length at 120 kHz consistently overestimates target strength', and that 'measurements over a range of animal lengths imply a stronger dependence of target strength on length than that predicted by the BIOMASS definition' (SC-CAMLR-X 1991). Although the Greene et al. (1991) equation is a currently accepted estimator of krill target strength, body shape, orientation and physical condition also affect target strength (Stanton 1989). The range of variation of these parameters should be measured under conditions when the krill would be surveyed, and used in theoretical models to predict the distribution of individual target strengths that would be expected from a natural aggregation of krill (SC-CAMLR-X 1991).

Estimates of krill biomass density are insensitive to minor variations in the frequency distribution of length. This is because the number of krill per kg

decreases exponentially with increasing length at approximately the same rate as the backscattering cross-sectional area of a single krill increases with increasing length. The dependence of weight, numbers per kg, target strength per individual, target strength per kg, backscattering cross-sectional area per kg and kg per $m^2$ of backscattering area on standard length are illustrated in Table 2 and Fig. 7a to e. As can be seen from Table 2, the factor relating krill biomass to backscattering area varies from 529 to 443 kg $m^{-2}$ of backscattering area over a range of krill lengths from 20 to 60 mm. This implies that mean length may be used to calculate biomass densities without introducing substantial errors. If, on the other hand, numerical densities are desired (e.g. for studies of foraging behavior) then body length is critical to accurate estimates.

Species identification is problematic. Several high-resolution Multiple Opening-Closing Net and Environmental Sampling System (MOCNESS) tows were aimed at specific echogram types. Swarming krill appear quite different from the other major sources of zooplankton sound scattering (other euphausids, primarily *Thysanoessa macrura*; amphipods, primarily *Themisto gaudichaudii*; copepods; and salps): the edges of krill swarms, although irregular, are very sharp and distinct, and the volume backscattering strength of krill aggregations is much higher than that for other taxa. Although the total number of non-krill zooplankton caught in the IKMT tows exceeded that of

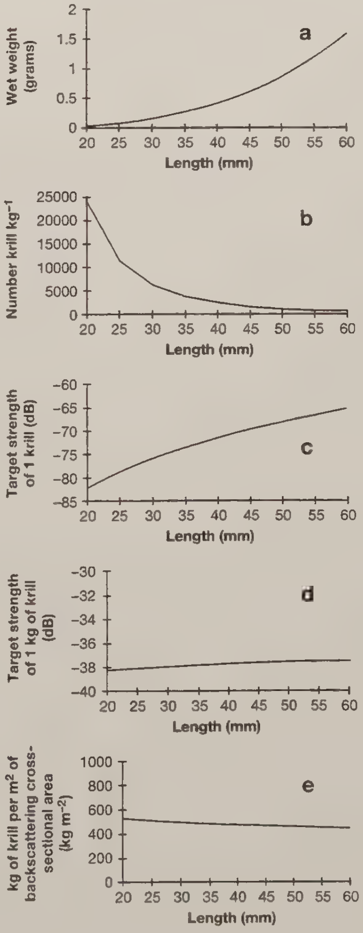

Fig. 7. *Euphausia superba*. Dependence of (a) krill weight, (b) numbers per kg, (c) target strength per individual, (d) target strength per kg, and (e) kg per backscattering cross-section, on standard length

krill (Loeb et al. 1992), their aggregate backscattering strength, estimated by assuming that target strength of elongated zooplankton is proportional to the cube of their length (Wiebe et al. 1990), was less than 10 % of that from krill over the survey area. Backscattering from krill and non-krill zooplankton were lumped together and biomass estimates are thus biased slightly upward. Although *Salpa thompsoni* were the most abundant non-krill zooplankton, they were not included in the above calculation because as gelatinous tunicates they are unlike any taxa included in Wiebe et al. (1990) experiments. Because they are mostly water and lack a strong density contrast, salps are probably not efficient sound scatterers. Although the numerical density of salps was higher than that of krill in IKMT samples collected in the southern and eastern portions of the large-area surveys, the integrated backscattering strength in these areas was low.

Krill within 10 m of the surface, below 250 m, and more dispersed than a threshold density of approximately 0.1 krill $m^{-3}$ were not detected and thus not included in the biomass estimates. Survey effort was not adjusted for the time of day so that the amount of undetected krill could have varied with diel changes in krill behavior. Ship's position was independent of time of day, however, and any diel effects should be random error added to the estimate of systematic bias caused by undetected krill. There were occasions when surface swarms were observed during daylight hours; and krill were sometimes entrained in the ship's cooling water intake during the day, although more frequently at night. The amount of krill in the upper 10 m, however, can be a substantial, but unknown, portion of that in the entire water column, and a potentially large source of error. This region could be investigated by using side-looking and up-looking transducers. In their review, Miller & Hampton (1989) note that krill are principally found in the upper 150 m of the water column. The lack of evidence to the contrary, however, does not preclude substantial numbers of krill below 250 m depth. Lower frequency echo sounders, acoustic transducers mounted on remote vehicles, and/or deeper fishing nets could be used to detect krill deeper than 250 m. The maximum density of undetected dispersed krill, assuming a density of 0.1 krill $m^{-3}$ throughout the upper 250 m and an average individual weight of 0.5 g, is less than 10 % of the average density of the 4 surveys. It is very unlikely that undetected krill would be present throughout the water column at just below the threshold density, and thus errors due to non-detection of dispersed krill are considered negligible.

Foote (1983) demonstrated that it was reasonable to assume that volume backscattering strength from fish schools was the result of incoherent addition of echoes from individual fish within the sample volume. The linear relationship between backscattering strength and density breaks down, however, at very high animal densities due to the effects of shadowing and multiple scattering (MacLennan & Simmonds 1992). Although peak $s_V$ values indicated krill densities on the order of $10^3$ ind. $m^{-3}$, shadowing may have occurred, particulary with thick swarms and layers. Evidence of multiple scattering was observed occasionally in association with very dense swarms. This ringing, observed as diffuse echoes below the more solid return from the swarm, was included in the integration with the expectation that multiple scattering helps offset the effect of shadowing (Stanton 1983).

Calibration inaccuracies can also contribute to the error in integration survey results. Foote & MacLennan (1984) stated that precision calibration to within 0.5 dB is possible by using standard calibration spheres. This translates to a 1 dB error in estimating mean target strength. Robinson (1984) noted that the acoustic absorption coefficient at 120 kHz is not known better than ± 0.5 dB $km^{-1}$. This implies that, at a range of 50 m, calibration accuracy can be no better than ± 0.5 dB due to this parameter alone. Our calibration experiments using various pulse lengths and sphere materials indicated system gain variations of as much as 1.2 and 1.5 dB, respectively (Demer & Hewitt in press).

Application of Jolly & Hampton's (1990) formula for estimating variance is valid only if the parallel survey transects are randomly spaced. Because the intent was to derive distribution maps as well as estimate abundance, transects were regularly spaced and Jolly & Hampton's expression for variance was used as an approximation. As such it is an underestimate of the true survey sampling variance.

The range of estimates of krill abundance in the Elephant Island area reported here is within the range of previously reported values. Macaulay et al. (1984) estimated that 2.1 million t of krill were aggregated in a large swarm located over the shelf break north of Elephant Island. Acoustic surveys conducted by Macaulay in the austral summers of 1981, 1984, 1987, 1988 and 1989, when normalized to a survey area of 5055 n $mile^2$ centered on Elephant Island, resulted in biomass estimates of 0.8, 0.3, 0.7, 0.5 and 0.9 million t respectively (Macaulay unpubl.). Macaulay (pers. comm.) assumed the target strength of 40 to 45 mm krill to be −35.93 dB $kg^{-1}$; incorporating the more recent definition of krill target strength (−37.70 dB $kg^{-1}$, Table 2) results in adjusted biomass estimates of 1.2, 0.4, 1.0, 0.7 and 1.4 million t. Klindt (1986) reported biomass estimates from combined acoustic and net surveys conducted in the Elephant Island area during 1983, 1984 and 1985 of 0.05, 0.4 and 0.02 million t respectively. Klindt used the BIOMASS (1984) definition

Table 3. *Euphausia superba*. Acoustic estimates of krill biomass in the Elephant Island area

| Year | Month | Survey area (n mile$^2$) | Biomass ($\times 10^3$ t) | Adj. biomass ($\times 10^3$ t) | Source |

[a] Excluding biomass of observed superswarms

of target strength adjusted to 150 kHz and the length frequency distributions reported by Siegel (1986a). Klindt's biomass estimates may be adjusted by a factor corresponding to the difference in target strength at 120 kHz using the modal krill lengths for each of the surveys (30, 41 and 45 mm); the corresponding factors (9.2, 5.8 and 4.9) result in adjusted biomass estimates of 0.5, 2.2 and 0.1 million t. Four surveys were conducted by Macaulay in the Elephant Island area during January and February 1990 (Amos et al. 1990). Estimated krill biomass increased from the first survey through the fourth survey (0.5, 1.1, 2.1 and 2.4 million t). Two surveys were conducted by Macaulay between mid-January and mid-February 1991 (Macaulay & Mathisen 1991). Estimated krill biomass increased from 0.7 to 0.8 million t. For the 1990 and 1991 surveys, Macaulay (pers. comm.) again used $-35.93$ dB kg$^{-1}$ to scale his biomass estimates; adjusted biomass estimates are 0.7, 1.7, 3.2 and 3.7 million t for 1990, and 1.0 and 1.2 million t for 1991. Results from the above surveys are summarized in Table 3.

Krill abundance in the Elephant Island area decreased over the 2 mo observational period of mid-January to mid-March 1992. Krill abundance decreased approximately 2-fold between the 2 large-area surveys, Surveys A and D, conducted in the waters surrounding Elephant Island. Krill abundance also decreased approximately 2-fold between the 2 small-area surveys conducted to the north of Elephant Island, Surveys B and C. This was in marked contrast to the results from surveys conducted in 1990 and 1991 when krill abundance increased from mid-January to mid-March.

Over the last 3 yr, several measures of reproductive success of chinstrap penguins *Pygoscelis antarctica* at Seal Island varied in concert with estimates of krill biomass: moderately high in 1990, very low in 1991, and very high in 1992 (D. A. Croll pers. comm.). Seasonal variations in the availability of krill to predators may also be important. Although average abundances of krill during the 1990 and 1992 austral summer were similar, the seasonal timing of peak abundance was quite different – late in 1990, early in 1992. Reproductive success of chinstrap penguins was high in 1992 relative to 1990. Good breeding success early in the 1992 season, however, may be countered by the lack of krill late in the season when local demand for prey by newly fledged chicks and adults about to molt may be at its highest (Croll in press).

*Acknowledgements.* This work was supported by the National Oceanic and Atmospheric Administration as part of its Antarctic Marine Living Resources (AMLR) program. We thank Duncan McGehee, Jane Rosenberg, Stephanie Sexton and Rennie Holt for their assistance in collecting the acoustic data; Valerie Loeb for providing data on the size distribution of krill; and the officers and crew of the NOAA Ship 'Surveyor' for their help and support. Helpful comments were also received from 3 anonymous reviewers.

ABSTRACT: A field study was conducted in May 1988 to estimate mortality rates of individual cohorts of larval walleye pollock *Theragra chalcogramma* in Shelikof Strait, Gulf of Alaska. Two surveys of the area of larval distribution were done 12 d apart and daily mortality rates estimated from changes in abundance of each cohort. This study was designed to minimize potential sources of bias to mortality estimates, such as larval extrusion or escapement from sampling gear, advective or diffusive gain or loss of larvae into or out of the sampling area, the uncertainty incurred by the use of length as a proxy for age, and the often erroneous assumption of constant production and mortality rates. The age-specific mortality rates from this study were low compared to rates previously estimated for larval walleye pollock. Four significant mortality estimates, ranging from 0.041 to 0.076 $d^{-1}$, came from among the youngest cohorts. The low larval mortality rates in 1988 coincided with very calm ocean conditions. Larval drift rates estimated in this study were coherent with the movement of a satellite-tracked drift buoy and averaged 3.1 to 3.9 cm $s^{-1}$, which is comparable to rates reported from other studies.

## INTRODUCTION

One of the most challenging problems in marine research is the estimation of mortality rates of organisms. This is particularly the case with planktonic early life stages of marine fishes due to the broad spatial and temporal scales of their distribution, their movement with currents, other sampling difficulties, and nonconstant birth rates (i.e. often peaked spawning cycles). It is frequently inappropriate to assume a stable age distribution and constant mortality rates to justify use of catch curve analysis (Ricker 1975, Hewitt & Methot 1982). Knowledge of mortality rates of marine fish eggs and larvae is a key to understanding the recruitment process of marine fishes because, for many species, the magnitude of recruitment may be established during early life stages (Houde 1987, Sundby et al. 1989, van der Veer et al. 1990). Accurate measurement of the magnitude and variability of mortality rates in the field is required to assess the causes and processes of mortality, such as predation and nutrition. Data on interannual variation in mortality rates can also be instrumental in forecasting year-class success.

We describe a method used to estimate the daily mortality rates for larval fishes from a population characterized by highly aggregated spawning that occurs over a short period of time. Walleye pollock *Theragra chalcogramma* spawning in Shelikof Strait (Alaska) occurs largely within a 1 mo period (Kim & Kendall 1989, Kendall & Picquelle 1990, Picquelle & Megrey in press). Larvae live in the upper 100 m of the water column and are advected to the southwest for several weeks in the Alaska Coastal Current (ACC) (Hinckley et al. 1990, Kendall & Picquelle 1990) and larval distributions are relatively predictable in time and space.

We have identified cohorts of larval walleye pollock from their hatch-date distributions as determined from daily growth increments on otoliths and have sampled

© Inter-Research 1993

the population twice, ca 12 d apart, to estimate mortality rates for each cohort. Larval transport was estimated from movement of several main patches of cohorts, from the displacement of centroids of the entire larval distribution, and from a satellite-tracked drift buoy (drogued at 40 m, the depth of highest larval abundance) released in the center of one of the main larval concentrations. Advection of larvae across the boundaries of the sampling grid was estimated from a model of advection and diffusion.

## METHODS

**Survey design.** Data from larval walleye pollock surveys of Shelikof Strait in 1986 and 1987 were examined to set the overall boundaries of the sampling area used in the present study and to estimate the likely abundances of larvae. An analysis of these data was used to estimate the number of stations needed to detect a reasonable minimum mortality rate. A power analysis (Zar 1984), using an estimate of variance of larval abundances in 1986 and 1987, indicated that, for a power of 0.8 and 0.95, a sample size of 50 stations per pass would detect overall mortality rates of 0.029 and 0.037 $d^{-1}$, respectively. These appeared to be reasonable lower limits of larval mortality which might be expected.

A stratified survey design was used for both passes. A stratification scheme for the first survey of the area (Pass 1) was based on prior information. Historically, high densities of larvae have been observed between Sutwik Island and the Semidi Islands (Fig. 1a). We also expected high densities in the inshore area north of Sutwik Island. Five strata were included in Pass 1 (Fig. 1a). The 7 strata for the second survey (Pass 2, Fig. 1b) were determined from the shipboard counts of the larvae found in Pass 1. The high inshore abundances found in Pass 1 were predicted to move to the southwest with the prevailing current; therefore the Pass 2 survey was extended further to the southwest.

The cruise was conducted from the NOAA vessel 'Miller Freeman' between 19 May and 9 June 1988. A grid of stations 9 or 19 km apart was established as described above and refined based on larval surveys of prior years, and from results of egg and larval cruises in April and May 1988. This grid was occupied from 21 to 24 May (Fig. 1a, Pass 1) and was resampled from 1 to 6 June (Fig. 1b, Pass 2). The mean date of each pass was separated by 12 d.

Three sets of gear comparisons were done – on 20 May, 30 May and 6 June – to examine catch rates by fish size for an estimate of larval escapement and avoidance of gear. The gears tested were a 60 cm bongo net with 0.333 mm mesh, a 1 m Tucker trawl with 0.505 mm mesh, a 3 m Tucker trawl with 1.5 mm mesh, and a Methot frame trawl with 2 × 3 mm oval mesh (Methot 1986). This range of gear types and mesh sizes has been shown to catch walleye pollock ranging from ca 4 to 40 mm standard length (SL) (M. Shima & K. Bailey unpubl.). Two daytime tows and 1 or 2 nighttime tows were done with each gear type. Each set of gear comparisons was located in an area of relatively high (>250 larvae 10 $m^{-2}$) abundance, and took ca 24 h to complete. All hauls for a particular set of gear comparisons were done at the same location.

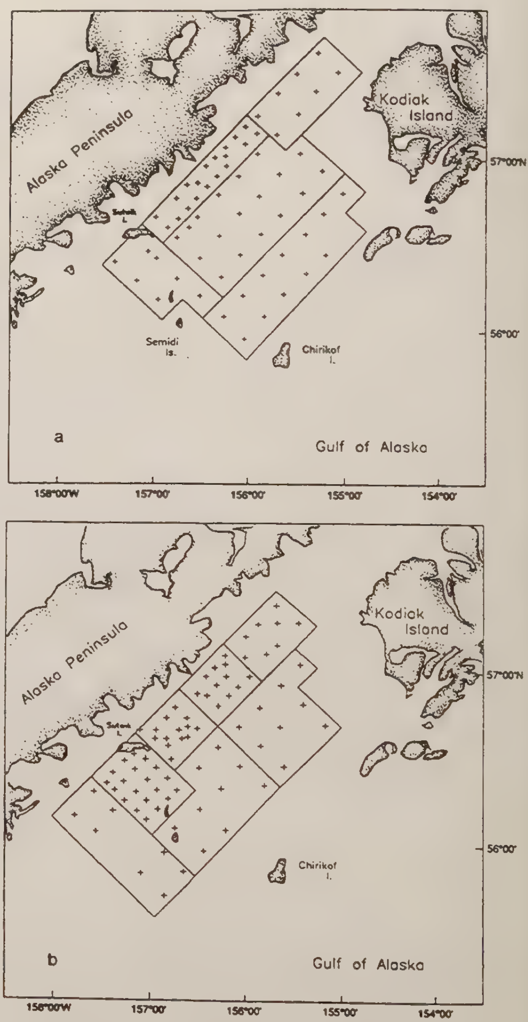

Fig. 1. Survey area for (a) Pass 1 and (b) Pass 2, including station locations and strata boundaries

The first set of gear comparison tows (20 May) indicated that the Tucker trawl was the most efficient in catching the size range of larvae observed (4 to 15 mm SL). It was therefore chosen as the standard gear for the larval surveys. Oblique tows were done to a depth of 100 m, as prior work has shown that larvae are above 100 m at this time of year (Kendall et al. 1987). The ship's speed was approximately 2 to 2.5 knots. A flow meter was used to normalize catch for volume filtered. The Tucker trawl was deployed with the net closed, and a messenger was sent to open the net when it reached sampling depth. The net was then retrieved at 20 m $\text{min}^{-1}$.

A subsample of walleye pollock larvae was removed from the cod end and immediately preserved for special studies. This subsample included larvae which were preserved in 95 % ethanol for daily growth increment analysis. In order to find areas of high concentrations of larvae for further special studies and to find the boundaries of the larval distribution (to ensure that the complete larval distribution was sampled), a volumetric subsampling method was used on the remainder of the catch to estimate the total number of larvae. The remaining contents of the cod end, aside from larvae removed for special studies, were preserved in 5 % buffered formalin. These samples were later resorted for a final count of walleye pollock larvae, which included those that had been removed for special studies.

**Analytic methods.** The number of larvae per tow was converted to number of larvae per 10 $m^2$ using a standard haul factor (Smith & Richardson 1977). Total number of larvae per pass was the sum over all strata of the stratum mean multiplied by the area of the stratum.

***Gear comparisons:*** For each of the 3 sets of gear comparison tows, catch rates by larval size interval were compared among gear types to test whether significant numbers of small or large larvae were missed by the sampling gear, and to examine catching efficiency by larval size. The number of larvae per 10 $m^2$ per 1 mm SL interval for each of the gear comparison tows was averaged by gear type. A Kolmogorov-Smirnov test (K-S; Zar 1984) was done to assess the difference in catch rates between the bongo net and the 1 m Tucker trawl.

An analysis of variance (ANOVA) of 1 m Tucker trawl catches was done to test whether catch rates differed between day and night (indicating gear avoidance). The catch per 10 $m^2$ at each survey station was log-transformed to equalize the variance. The factors in the ANOVA were strata and day/night. Two strata from Pass 1 were excluded because they contained only stations done during the day.

***Length-frequency and shrinkage:*** The standard length of 50 walleye pollock larvae per haul (Passes 1 & 2) was measured from a combination of ethanol-preserved larvae, formalin-preserved larvae, and larvae measured before preservation. Larval lengths from each preservative type were combined in order to construct an unbiased length-frequency file. Biases by preservative type were due to selective removal of larvae (by size) for special studies. The number of larvae measured from each preservative type was proportional to the total number of larvae which had been placed in that preservative. Samples from each preservative type were random. Lengths of larvae from different preservative types were converted to fresh (pre-fixation) lengths using the following relationships:

$$(\textit{95\% ethanol})\ \text{Fresh length} = \frac{\text{Fixed length} - 0.349}{0.900},$$

and

$$(\textit{5\% formalin})\ \text{Fresh length} = \frac{\text{Fixed length} - 0.097}{0.900}.$$

These relationships were derived from experiments [in 1988 and other years; D. Seifert, Alaska Fisheries Science Center (AFSC), 7600 Sand Point Way NE, Seattle, WA 98115, USA, pers. comm.] where fresh length and preserved length were measured on the same fish. Converted lengths were combined into an overall length-frequency for each pass.

***Aging:*** Approximately 15 to 20 fish per station from about 15 stations per pass were aged from otoliths by enumerating daily growth increments (Yoklavich & Bailey 1990). Daily growth increments have been validated by laboratory studies for this species (Nishimura & Yamada 1984, Bailey & Stehr 1986). Growth was linear over the size range (4.7 to 18.2 mm) examined ($R^2 = 0.90$).

An analysis of covariance (ANCOVA) was done to test differences in growth over the study period and area. The ANCOVA included length as a dependent variable, stratum as a categorical variable, and age as the covariate, and included an age-stratum interaction term. The analysis showed that the slope of the age-length regression (over the common range, 5 to 18 mm) did not vary significantly among stations over the survey area ($p = 0.919$). Within each pass, pair-wise tests of the equality of the intercepts (using Bonferroni probabilities; Miller 1981) of the length-age regression among strata showed that within Pass 1, 4 of the 5 pairs of strata tested had the same intercept ($p > 0.05$), while 1 was statistically different ($p < 0.05$). However, this difference was small and we considered it insignificant. Within Pass 2, the intercepts were the same among strata. Growth rates within each pass were therefore treated as equal.

***Mortality estimation:*** An age-length key (Kimura 1977) was computed for each pass. There were 309 larvae aged from Pass 1 and 249 larvae aged from

Pass 2. The elements in each row ($q_{la}$) of the key are the proportion of fish in length interval $l$ that are age $a$, thus each row is the age distribution for the length interval. Each element in the matrix is used to estimate the proportion of length $l$ larvae in the population that are age $a$. Age and length intervals were chosen to cover the range of the aged larvae (length ranged from 3 to 22.5 mm, age ranged from 6 to 62 d). The interval size must be large enough to contain enough larvae in the sample to produce reliable estimates of the true proportions in the population. In this application, length intervals of 0.5 mm were used. Daily ages were desired, but this resulted in too many age intervals for the number of aged larvae, so age intervals of 3 d were used. Additionally, the use of age intervals less than 3 d would not be justified as the measurement error in the aging process was ±1 d.

An age-length key was used for this study rather than an estimated age-length relationship for converting length-frequencies into age-frequencies. This is necessary because fish of a specific cohort may be missing from the population but could be misidentified in the length composition due to the averaging effect of the model. An age-length key preserves the shape of the age distribution present in the aged subsample, which is assumed to be a precise representation of the true age distribution if the aged subsample is unbiased.

The standardized catch of larvae at each station was partitioned into 3 d cohorts based on the length distribution at the station and the appropriate age-length key. Cohorts were defined by the age of the larvae on the mean date of the pass. For example, the mean date for Pass 2 was day-of-the-year (DOY) 155, so a larva sampled on DOY 153 with an estimated age of 22 to 24 d would be assigned to the 24- to 26-d-old cohort, its age on DOY 155. This age adjustment for the day of sampling was necessary because the duration of each pass (5 d) was longer than the duration of a cohort (3 d).

The total number of larvae in each cohort for each pass was computed by summing the estimated cohort totals from each stratum. The cohort totals for each stratum were estimated by averaging the estimated number of larvae from each station in the cohort over stations, then multiplying the average by the total area of the stratum.

$$C_{ha} = \sum_{i} C_{hia}$$

$$C_{hia} = A_{hi} \sum_{j}^{N_{hi}} \frac{C_{hiaj}}{N_{hi}}$$

where $C_{ha}$ = estimated abundance of cohort $a$ in Pass $h$; $C_{hia}$ = estimated abundance of cohort $a$ in stratum $i$ in Pass $h$; $C_{hiaj}$ = estimated no. of larvae in cohort $a$ per 10 m$^2$ at station $j$ in stratum $i$ in Pass $h$; $A_{hi}$ = area of stratum $i$ in Pass $h$ in units of 10 m$^2$; and $N_{hi}$ = no. of stations in stratum $i$ in Pass $h$.

The variance of the estimated cohort totals has 2 components: the variability about the standardized catch sizes within each stratum and the uncertainty about the age distribution. This uncertainty is due to using an age-length key to estimate the age of the larvae rather than measuring the age of each larva directly. Kimura (1977) estimated variance of an age distribution from an age-length key; however, in the present application, the age distribution variance was complicated by the fact that a cohort is comprised of larvae from different age intervals corresponding to the different sampling dates. Therefore, an estimator for the variance about a total of a range of ages was used (S. J. Picquelle, ASFC, pers. comm.). Covariance between the estimates for a cohort from the 2 passes is assumed to be zero because these estimates are taken from 2 surveys which are statistically independent.

Mortality rates were estimated for each 3 d cohort that was present in both passes. Cohorts represented by very few fish in the age-length key (i.e. very young and very old fish) were dropped from the mortality analysis, as they were suspected of being underrepresented in the catch. The mean dates of the 2 passes were separated by 12 d. An exponential function was used to estimate cohort-specific mortality rates over the 12 d.

$$C_{2,a} = C_{1,a}\, e^{-z_a(t_2 - t_1)}$$

$$z_a = \frac{\ln(C_{1,a}) - \ln(C_{2,a})}{t_2 - t_1}$$

where $z_a$ = estimated instantaneous daily mortality rate for cohort $a$; $t_2 - t_1$ = time between passes (12 d); $C_{1,a}$ = estimated abundance of cohort $a$ in Pass 1; and $C_{2,a}$ = estimated abundance of cohort $a$ in Pass 2.

This model was also used to calculate the instantaneous daily mortality rate for the combined 10 April to 16 May cohorts.

The variance of the mortality rate was estimated using the delta method (Seber 1982).

$$Var(z_a) \approx \frac{1}{(t_2 - t_1)^2}\left[\frac{Var(C_{1,a})}{C_{1,a}^2} + \frac{Var(C_{2,a})}{C_{2,a}^2}\right]$$

where $Var(z_a)$ = approximate estimate of variance about the mortality rate for cohort $a$; and $Var(C_{h,a})$ = estimate of the variance about the estimated abundance of cohort $a$ in Pass $h$ (Picquelle pers. comm.).

The significance of the mortality coefficients could have been tested with a simple $t$-test, however, the variance of the mortality rate is an approximation. Therefore, the significance of the mortality rate was inferred through the use of a test of the difference in abundance of each cohort between Passes 1 & 2. This was a 2-tailed test where the variances of the abundances were not assumed to be equal and the critical value for the test was a weighted average (Sokal & Rohlf 1981).

Biases to the mortality estimates caused by advective transport into or out of the study area were examined by a model of advection and diffusion developed for this area (P. Stabeno & L. Incze, NOAA, Pacific Marine Environmental Laboratory (PMEL), 7600 Sand Point Way NE, Seattle, unpubl. data). The model is a 2-dimensional (depth-integrated) finite difference model with an imposed velocity field, that contains terms for larval mortality and age-dependence:

$$\frac{\partial C}{\partial t} = -U\frac{\partial C}{\partial x} - V\frac{\partial C}{\partial y} - K_H\left(\frac{\partial^2 C}{\partial x^2} + \frac{\partial^2 C}{\partial y^2}\right) - Q(a,x,y,t)$$

where $C$ = the depth-integrated concentration of larvae; $t$ = time; $U$ = cross-strait horizontal velocity; $x$ = cross-strait axis; $V$ = along-strait horizontal velocity; $y$ = along-strait axis; $K_H$ = horizontal coefficient of eddy diffusivity; $Q(a,x,y,t)$ = the larval source and sink term (i.e. hatching and mortality); and $a$ = larval age.

The concentration of larvae was assumed constant normal to the model boundaries [$C(x,y,t) = 0$]. The horizontal velocities and coefficient of eddy diffusivity (which is assumed constant) were determined using drift buoy and current meter data. The only biological input into this model was an age-dependent mortality which enters via the $Q(a,x,y,t)$ term.

Larval concentrations measured during Pass 1 were used as initial input to the model. The age-dependent mortality used was from Yoklavich & Bailey (1990). The model was run for 12 d with the mean observed current field (as derived from satellite-tracked buoys; P. Stabeno & R. Reed, NOAA, PMEL, unpubl. data). The percent of larvae expected in the region covered in Pass 2 was predicted from the model output. For the mortality estimation, survey boundaries for Pass 2 were adjusted to reflect the area where more than 95% of the larvae were predicted to be by the model 12 d after the mean date of Pass 1.

As an alternative, mortality rates derived from the age composition within each pass were also calculated via catch curve analysis (Ricker 1975) for comparison to those derived from the 2 passes. Assumptions made when using this method are that production of fish of all ages is constant, that mortality rate for all ages is also constant, and that all ages are equally vulnerable to sampling gear. Total mortality rates, over all ages, from the catch curves within each pass were calculated from a regression of log abundance on age:

$$\ln(C_{ha}) = \alpha_h - z_h t_a$$

where $C_{ha}$ = estimated abundance of cohort $a$ in Pass $h$; $t_a$ = age of cohort $a$; $\alpha_h$ = intercept for Pass $h$; $z_h$ = estimated instantaneous daily mortality rate for Pass $h$.

***Larval drift:*** Larval spatial distributions were contoured separately for each 3 d cohort for each pass. These plots were examined for patterns of distribution and for evidence that part of the larval distribution might have been missed in either Pass 1 or Pass 2 (indicated by high concentrations of larvae near the survey boundaries), thereby biasing the mortality estimates. Drift of larvae between Passes 1 & 2 was measured by assuming coherence of 3 major observed larval patch features, and by measuring the net movement of these patches between the passes.

Centroids, a measure of the center of mass of the larval distribution computed by using abundances at each station weighted by the locations of the stations (Kendall & Picquelle 1990), were calculated for all larvae from each pass. Centroid locations were corrected for irregular sampling distribution (with more stations in the inshore areas) by weighting each station location not only by larval density, but also by the area each station represented. Net displacement of the centroids of larval distribution was calculated for the interval between the 2 passes.

The 2 estimates of larval drift (from patch displacement and centroid displacement) were compared to the estimates of upper-water-column movement derived from a satellite-tracked drift buoy that was released in an area of larval concentration near the Alaska Peninsula during Pass 1.

## RESULTS

### Day/night catch comparison and catchability

Catch rates of walleye pollock larvae did not vary significantly between day and night (ANOVA, p = 0.56, Table 1). There was no consistent pattern of catch in the day or the night. The strata effect was highly significant (ANOVA, p = 0.0003, Table 1).

Table 1. Analysis of variance of log-transformed catch rates (no. of larvae $10\,m^{-2}$) of the 1 m Tucker trawl using strata and day/night as factors

| Source | df | Mean square | $F$ | p |
|---|---|---|---|---|
| Strata | 9 | 2.7509 | 3.89 | 0.0003 |
| Day/night | 1 | 0.2462 | 0.35 | 0.5562 |
| Interaction | 9 | 0.8936 | 1.26 | 0.2639 |
| Error | 112 | 0.7064 | | |

The catch rates of the bongo and the 1 m Tucker trawl did not differ significantly (K-S test, $p = 0.89$). Other work on catchability of larvae by these gear types (Shima & Bailey unpubl. data) has also shown no consistent pattern of differing efficiency over this larval size range. The gear comparison experiments showed that the 1 m Tucker trawl was effective in catching the entire length-range of larvae that were caught by the other gear (Fig. 2). The 3 m Tucker trawl and the Methot trawl caught less than the bongo and the 1 m Tucker because of their large mesh sizes. There were not significant numbers of smaller larvae in the 0.333 mm mesh bongo, or larger larvae in the larger mesh 3 m Tucker or Methot trawls. Therefore, no correction of abundance estimates for escapement or avoidance was made to the survey station catches made with the 1 m Tucker trawl.

### Model of advection and diffusion

Estimates of probable changes in larval distribution derived from the application of the advection and diffusion model resulted in dropping the 2 northernmost stations from the Pass 2 survey. Larvae found at these 2 stations would have been upstream of the survey area in Pass 1 and therefore would have been advected into the Pass 2 survey area. Otherwise, the boundaries for Pass 2 were not changed, as the model predicted that more than 95 % of the larvae found in Pass 1 would be found within the area covered during Pass 2.

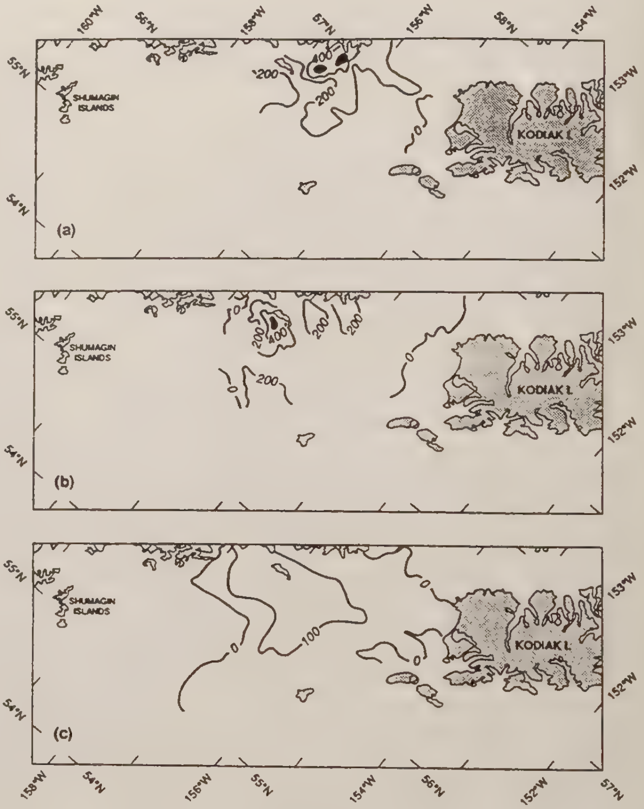

Fig. 3. The domain of the model is shown. Distribution of larvae (a) found during Pass 1 (this is the initial condition for the model), (b) found during Pass 2, and (c) predicted by the model of advection and diffusion for the time period corresponding to Pass 2. Larval abundance contours shown are ind. 10m$^{-2}$ (solid area: >600 larvae 10m$^{-2}$)

Comparison of the larval concentrations predicted from the model and those observed on the second survey (Fig. 3) shows that patch structure observed in the field was not preserved due to diffusion in the model, for all reasonable values of diffusivity ($K_H > 5 \times 10^5$ cm$^2$ s$^{-1}$).

### Mortality rates

Abundances of the 10 April through 16 May cohorts were used to estimate mortality rates. Abundances for the 10 through 28 April cohorts were very similar between Passes 1 & 2. Abundances of fish with hatch dates between 1 and 16 May showed a clear decline in abundance from the first to the second pass (Fig. 4).

The instantaneous daily mortality rates ($z$) for the separate 3 d cohorts ranged from −0.0574 to 0.0757 d$^{-1}$

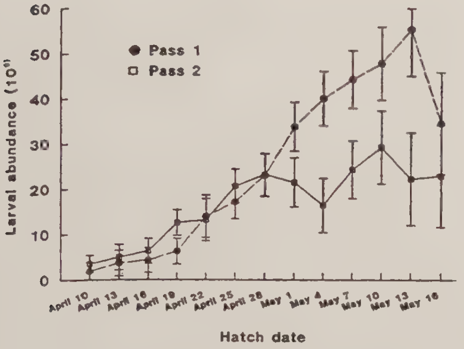

Fig. 4. *Theragra chalcogramma*. Larval abundance for 3 d cohorts during Passes 1 and 2

(Table 2). The instantaneous daily mortality rate for the combined 10 April to 16 May cohorts was $z = 0.033$ d$^{-1}$ ($Var(z) = 0.0013$). This mortality rate was not significantly different from zero ($t = 0.92$, $p > 0.20$).

Inspection of the cohort distributions for Pass 1 (Fig. 5) showed an area of relatively high concentration of larvae from the 10 to 19 April cohorts on the northwest side of the survey area near the Alaska Peninsula, which might not have been fully sampled. This was of interest due to the fact that the mortality rate estimated for these 4 cohorts were negative (Table 2). To test whether a significant number of larvae might have been missed in the inshore area during Pass 1 (which would have lowered the mortality rates for these cohorts), the northwest boundary of the survey area was redrawn closer to the Alaska Peninsula, increasing the total survey area for Pass 1. Larval abundances were extrapolated to the new boundary, and mortality rates recalculated using new total cohort abundances for Pass 1. The results of this analysis showed that, unless unusually high abundances of larvae were present in the nearshore areas outside the Pass 1 grid, extension of the survey area would not have been sufficient to raise the estimates of the mortality rates for these cohorts above zero (Table 3).

The overall daily mortality rate for each pass derived from the catch curve analysis was $z = 0.0838$ d$^{-1}$ for Pass 1, and $z = 0.0421$ d$^{-1}$ for Pass 2.

## Larval drift

Three main areas of concentration of larvae are visible in the distribution of the combined 10 April to 16 May cohorts in Pass 1 (Fig. 6a). Two patches were found to the northeast of Sutwik Island near the Alaska Peninsula ('Patch 1' and 'Patch 2'), and one was found to the northeast of the Semidi Islands ('Patch 3'). Three concentrations of larvae also are visible in Pass 2 (Fig. 6b), one to the northeast of Sutwik Island ('Patch 1'), one to the southwest of Sutwik Island ('Patch 2'), and one to the south of the Semidi Islands ('Patch 3'). Most of the 3 d cohorts were present in all 3 of these main patches in each pass.

There was an apparent southwestward displacement of all 3 patches over the interval between passes. By assuming the coherence of these 3 patches and measuring their displacement between the 2 passes, we could use their net movement over this time period as an estimate of the rate of larval drift. The time

*Significantly different from zero (α = 0.05)
**Significantly different from zero (α = 0.01)

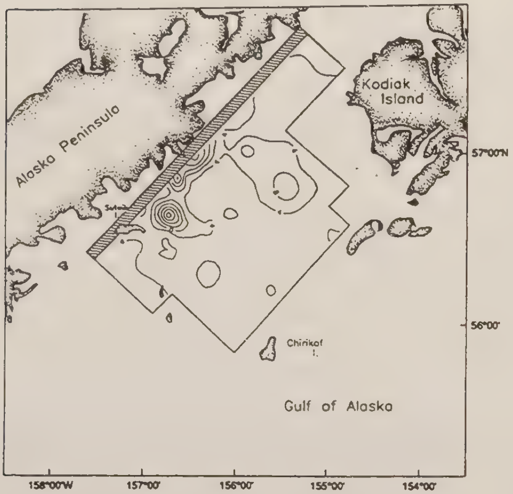

Fig. 5. *Theragra chalcogramma*. Distribution of the 19 April cohort during Pass 1 showing area on the northwest border of the survey area (shaded) where larvae might have been missed, causing underestimation of mortality rates. Larval abundance contours shown are ind. 10 $m^{-2}$

period over which movement was estimated was between the actual sampling dates at each patch rather than between the mean pass dates. Drift was calculated from the straight-line movement of patches between the 2 dates.

Patch 1 movement averaged 2.59 cm $s^{-1}$, Patch 2 averaged 3.61 cm $s^{-1}$, and Patch 3 averaged 5.29 cm $s^{-1}$. The average rate of drift for all 3 patches was 3.8 cm $s^{-1}$.

Rates of drift were also estimated from displacement of the centroids of the entire larval distributions for each pass. The location of the centroids for 1988 in Passes 1 & 2 were similar to 1981 and 1986 (Fig. 7). The centroid locations for 1979 and 1982 were further offshore. Centroid locations appear farther offshore than might be indicated by the distributions shown in the contour plots because the few high stations represented in the patches do not have a large impact on centroid locations, whereas they are interpolated over a larger area in the contour plots. The displacement of the centroids over the 12 d between mean pass dates suggests a rate of drift of 3.9 cm $s^{-1}$.

Table 3. *Theragra chalcogramma*. Results of increasing Pass 1 survey area on the northwest side of the grid and recalculation of daily mortality rates of the 10 to 19 April cohorts

| Hatch date | Mortality rate (uncorrected)[a] | Mortality rate (corrected)[b] | % Change in mortality rates |
|---|---|---|---|
| 10 Apr | −0.0494 | −0.0432 | +12.5 % |
| 13 Apr | −0.0254 | −0.0174 | +31.5 % |

| 19 Apr | −0.0574 | −0.0462 | +19.7 % |

[a] Using original Pass 1 survey boundary
[b] Using extended Pass 1 survey boundary

The net movement of the satellite-tracked buoy was compared to these 2 estimates of larval drift. The buoy was deployed on 24 May, near the center of Patch 1 (which was sampled at approximately this time) (Fig. 8). The buoy location on 31 May was close to the center of Patch 1 when it was sampled during Pass 2 (on 1 June). If only the period 24 May to 1 June was considered (corresponding approximately to the interval between the passes), the average velocity was 4.7 cm $s^{-1}$.

## DISCUSSION

Estimating larval mortality rates for marine fish is difficult due to the many sources of sampling bias and error. In this study, we have attempted to avoid many of the problems which have complicated earlier studies. Use of multiple surveys instead of the more usual catch curve analysis made it possible to avoid the assumptions of constant egg production and constant mortality. Comparisons of several gear types and day/night sampling indicated that retention and escapement of walleye pollock larvae from sampling gear was not a problem. Transport of larvae through the sampling area was accounted for by sampling virtually the entire distribution of walleye pollock larvae, and boundaries were refined through the use of a model of advection and diffusion developed for this area. By analyzing daily growth increments of otoliths, we avoided the uncertainty of using length as a proxy for age, ensured that the same cohorts were identified in each survey, and were able to estimate mortality rates for specific 3 d cohorts of larvae. Ageing also made it possible to truncate the range of cohorts that had estimated mortality rates to those that were adequately sampled in each pass. Also, Somerton & Koyabashi (1992) show that truncating the age distribution avoids bias due to low capture probabilities. Larvae hatched after completion of the first pass could also be excluded this way. Since virtually the complete vertical and horizontal distribution of larvae was sampled in this study, differences in spatial distribution of larvae, for example with age, were not a factor.

The range of mortality rates estimated from this study (−0.0574 to 0.0757) was low compared to other published mortality rates for walleye pollock during this developmental

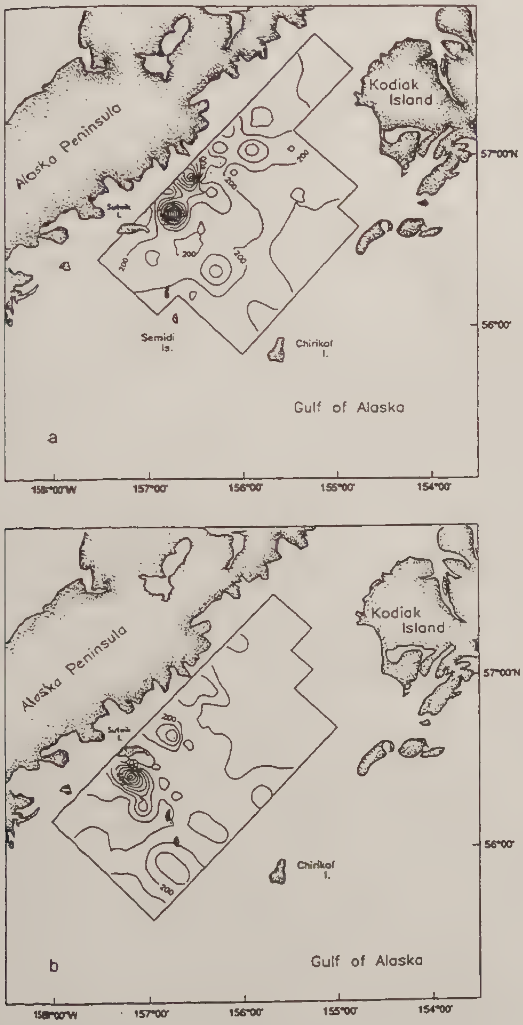

Fig. 6. *Theragra chalcogramma*. Distribution of 10 April to 1 May cohorts during (a) Pass 1 and (b) Pass 2. Larval abundance contours shown are ind. $10\,m^{-2}$

period. Rates from prior studies have ranged from $z$ = 0.065 to 0.11 $d^{-1}$ (Table 4). Estimates of mortality rates reported for the larval stage of other gadoids have also been also somewhat higher (e.g. for Atlantic cod: $z$ = 0.08 $d^{-1}$, Houde 1987; and $z$ = 0.12 $d^{-1}$, Sundby et al. 1989). The fact that the daily mortality rates for all of the 3 d cohorts were consistently low with none exceeding $z$ = 0.0747 $d^{-1}$ and that mortality rates determined from catch curve analysis were also low supports the conclusion that the low overall mortality rates found in this study were realistic.

In accordance with the low mortality rates observed for larvae, there is evidence that 1988 may be a relatively strong year-class for walleye pollock spawned in Shelikof Strait. There was a high relative abundance of 0-age juveniles caught in an August–September 1988 juvenile survey (Bailey & Spring 1992) indicating that recruitment was established early. Furthermore, the 1988 year-class has made a strong showing in the annual March hydroacoustic surveys of the Shelikof spawning stock in both 1990 and 1991 (Hollowed et al. 1991; J. Traynor, AFSC, pers. comm.). Low larval mortality rates during the spring of 1988 could have been a contributing factor to the strength of the year-class.

It is interesting to note that wind speeds during May of 1988 were much lower than normal for an extended period of time including the time period of this survey. The mean May wind speed (derived from atmospheric pressure gradients estimated from National Meteorological Center data) for 1988 was 4.63 m $s^{-1}$, whereas the average for May of 1980 to 1987 and 1989 was 6.70 m $s^{-1}$.) The mechanism explaining a relationship between wind speed and larval survival is not known, although several authors have speculated on possible causal relationships in other species (Lasker 1975, Sundby & Fossum 1989, MacKenzie & Leggett 1991).

Based on the power test done previously, we did not expect to resolve mortality rates below 0.037 $d^{-1}$ (for a power of 0.95). The 4 significant mortality rates were all greater than this (0.041 to 0.067 $d^{-1}$). Mortality rates of 9 of the 13 oldest cohorts were not significantly different from zero. There are several possible reasons for this. First, patchiness in the larval distribution could have caused the variance to be too large to make low mortality rates indistinguishable from zero. Better stratification and increased sampling in areas of high abundance could have reduced this source of variability. However, the patchy distribution of larvae and the uncertainty in predicting areas of high larval abundance make survey design difficult. Second, the fact that each pass was not synoptic (i.e. each took from 4 to 6 d to complete) and that the pass duration was greater than the duration (3 d) of each cohort caused an increase in the variance in the age-length key, as it was a composite from several days. Adding more passes and more days between the passes would be alternative ways to increase our ability to detect low rates of mortality. Third, there is high natural variation in the age-length relationship. A larger ageing sample would be helpful in reducing this source of variation. And fourth, although we tried to eliminate the possibility of advection of larvae into the survey area between Passes 1 & 2 through the survey design and use of the model of advection and diffusion, it is still possible that such immigration did occur.

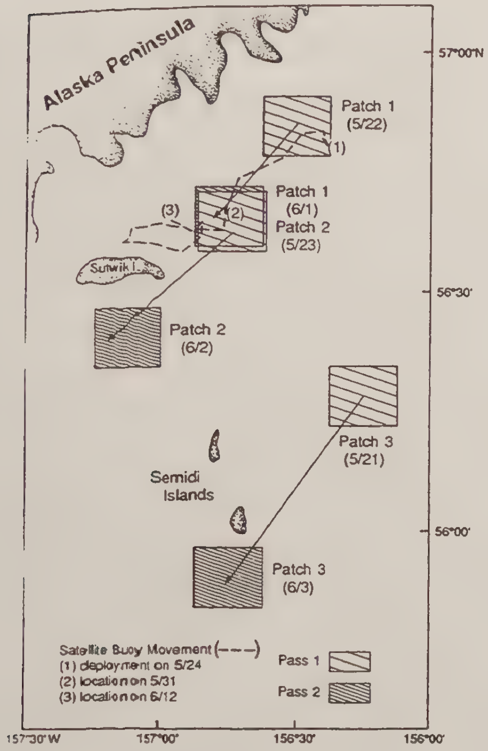
| This study | 0.033<br>($Var(z) = 0.0013$) | For combined 10 Apr to 16 May cohorts |

It is interesting to note that the 4 significant mortality rates were for cohorts of young larvae. Mortality rates actually are probably higher for young fish. A decrease in mortality rate with age or size is to be expected (Cushing 1974), and has been reported for walleye pollock larvae by Yoklavich & Bailey (1990).

The mortality rates for the older cohorts were very low, and this, combined with very high variance, made them statistically indistinguishable from zero. The lack of significance of the mortality rates for older cohorts could also be explained by an underestimation of the abundance of older larvae during Pass 1 or an overestimation during Pass 2, either of which would have caused an apparent decrease in the mortality rate (or negative rates). There was no increase in the variance of the mortality rate relative to the mean with age, indicating that the distribution of older larvae was not patchier (which would have increased the variation in abundance estimates; Pielou 1977).

Transport of larvae was examined by displacement of larvae, by satellite drifter trajectories, and by satellite imagery. During the spring, daily mean current speeds in Shelikof Strait have been measured from 10 to 50 cm $s^{-1}$ (Schumacher et al. 1989); however, the current structure in Shelikof Strait is complex in both time and space (Stabeno & Incze unpubl.). Circulation is dominated by the Alaska Coastal Current (ACC), a narrow (less than 20 km wide), buoyancy-driven current system. There is much variability in current speeds and location and direction of the ACC within the study area (Reed et al. 1989). Eddy-like features on the order of 20 km in diameter are common and add complexity to the current structure. Due to the complex wind regime, regions of wind-driven convergence and divergence are common. Both eddies and regions of wind-generated convergence probably play a role in the observed patchiness of larvae.

Larval drift rates estimated by several different methods were all similar. The average drift rate from these 3 methods was ca 3.1 to 3.9 cm $s^{-1}$. This rate is comparable to the larval drift rates estimated from other studies for larval walleye pollock (Incze et al. 1989: about 4 cm $s^{-1}$; Kim & Kendall 1989: 3.2 cm $s^{-1}$; Reed et al. 1989: 5 cm $s^{-1}$; Kim & Bang 1990: 3.13 cm



*Theragra chalcogramma*. Boxes show the locations of the 3 main concentrations of larvae (as seen in Fig. 6a, b) and their net displacement between passes. The track of the satellite-tracked buoy is also shown

$s^{-1}$). Other studies have estimated transport rates as high as 8 to 9 cm $s^{-1}$ (Incze & Campbell 1989, Incze et al. 1990).

Daily average velocities usually are weak (<10 cm $s^{-1}$) in the region near Sutwik Island and the Semidi Islands, the areas where the larval patches were found for this study. This flow is not in the ACC where currents can be as fast as 50 cm $s^{-1}$. The low net drift of the larvae in the patches was small because they are not in the ACC. The model of advection and diffusion was able to retain larval patches if an eddy was included in the current field (Stabeno & Incze unpubl.). Both cyclonic and anticyclonic eddies have been observed in the Shelikof Strait region several times during the past 5 yr (Vastano et al. 1992, Schumacher et al. 1993, Stabeno & Incze unpubl.) and larval patches appear to be associated with these eddies.

Also, it is notable that there was no apparent along-strait gradient of ages with older larvae further downstream, as might be expected if all cohorts were spawned in the same location (Kim & Kendall 1989, Kendall & Picquelle 1990) and no mechanism for retention of cohorts was present.

Inferences can be made about the patterns and velocities of surface flow based on sea surface temperature (SST) pattern displacements derived from satellite images (Vastano & Borders 1984). A preliminary examination of SST patterns for the survey period in May of 1988 (A. C. Vastano, Dept. Oceanography, Texas A&M Univ., College Station, TX 77843, USA, pers. comm.) showed a circulatory feature to the northeast of the Semidi Islands on May 23 to 24 and another to the south of the Semidi Islands on June 4 to 5. The direction of flow between these 2 surface features would be consistent with the assumption of coherence between the larval patch feature found in this area. It is not clear from satellite images whether any circulatory features existed in the Sutwik Island area during our study that could have entrained the buoy and the larvae. The SST photographs do, however, indicate several significant meanders in the surface flow, particularly during the Pass 1 time period. The images also indicate a pattern of surface flow along the Alaska Peninsula near Sutwik Island in the same direction as the movement of the buoy and the inferred drift of Patches 1 & 2.

Larval patchiness may play a significant role in overall rates of larval mortality. Patch-level studies of larval growth, feeding and predation, and their importance to larval survival are being conducted for walleye pollock. The techniques described in this study will also continue to be used to obtain age-structured mortality rates, which, along with studies of the mechanisms and causes of larval mortality of walleye pollock in Shelikof Strait, will promote a better understanding of the dynamics of the recruitment process for this stock.

In summary, realistic and precise rates of larval pollock mortality were estimated for individual cohorts during the period of downstream drift in 1988. These estimates were low compared to those from other years, coinciding with calm ocean conditions during the larval drift period, and corresponding to relatively strong recruitment of the 1988 year class. These data reinforce the concept that good larval survival is a necessary, but perhaps not sufficient, factor for development of strong year-classes. Smaller and younger cohorts experienced significant mortality over the 12 d period between sampling dates, while mortality of older and larger cohorts was insignificant. The results support the concept of intra-specific size-dependent mortality.

HIRUKI, L. M., GILMARTIN, W. G., BECKER, B. L., and STIRLING, I. 1993. Wounding in Hawaiian monk seals (*Monachus schauinslandi*). Can. J. Zool. **71**: 458–468.

Injuries observed on endangered Hawaiian monk seals (*Monachus schauinslandi*) at Laysan Island and French Frigate Shoals in the northwestern Hawaiian Islands in 1988 and 1989 were classified into six major types, based on the source of the wounds: mating attempts by adult male monk seals; nonmating aggressive interactions with other seals; attacks by large sharks; attacks by cookiecutter sharks (*Isistius brasiliensis*); contact with coral reef or debris; and entanglement in netting or marine debris. At both locations, injuries inflicted by adult male seals during mobbing incidents, in which many males attempt to mate with one seal, were seen more frequently than other types of injuries in 1988 and 1989. Injury data from 1982–1987 at Laysan Island and from 1985–1989 at French Frigate Shoals were used to compare the distribution of mating injuries inflicted by adult males and injuries inflicted by large sharks over size and sex classes of seals. Mating injuries caused by adult male seals were seen primarily on adult females but were also seen on seals in other size classes. Mating injuries inflicted by adult males occurred earlier in the year and with greater frequency at Laysan Island than at French Frigate Shoals. Injuries inflicted by large sharks were observed more often on adult male seals than on seals in other size classes at Laysan Island; however, no such difference was seen among size classes at French Frigate Shoals.

HIRUKI, L. M., GILMARTIN, W. G., BECKER, B. L., et STIRLING, I. 1993. Wounding in Hawaiian monk seals (*Monachus schauinslandi*). Can. J. Zool. **71** : 458–468.

Les blessures observées chez le Phoque-moine d'Hawaii (*Monachus schauinslandi*), une espèce menacée, à l'île Laysan et sur les hauts-fonds French Frigate dans le nord-ouest de l'Archipel hawaïen en 1988 et 1989 ont pu être classifiées, d'après leur origine, en six catégories principales : aggressions des mâles adultes durant les tentatives d'accouplement, interactions aggressives non reliées à l'accouplement chez les autres phoques, attaques de grands requins, attaques du requin *Isistius brasiliensis*, contacts avec le récif ou les débris coralliens et empêtrements dans les filets de pêche ou autres agrès. Aux deux sites, c'étaient les blessures produites par les mâles adultes durant les cohues, lorsque plusieurs mâles cherchaient à s'accoupler avec une même femelle, qui étaient les plus fréquentes en 1988 et 1989. Des données récoltées en 1982–1987 à l'île Laysan et en 1985–1989 aux hauts-fonds French Frigate ont permis de comparer la répartition d'après la taille et le sexe des blessures infligées par les mâles durant l'accouplement et celles dues aux requins. Les blessures causées par les mâles durant l'accouplement se retrouvaient surtout chez les femelles adultes, mais aussi chez des phoques d'autres classes de taille; à l'île Laysan, ces blessures pouvaient s'observer plus fréquemment et plus tôt dans l'année qu'aux hauts-fonds French Frigate. Les blessures dues aux grands requins apparaissaient plus couramment sur les adultes mâles que sur les autres phoques à l'île Laysan, mais non aux hauts-fonds French Frigate.

## Introduction

Injuries are generally considered detrimental to animals, for they can reduce the probability of survival (Congdon *et al.* 1974; Willis *et al.* 1982) or delay maturation (Maiorana 1977). Various types of scars and fresh injuries are seen on Hawaiian monk seals (*Monachus schauinslandi*) (Kenyon and Rice 1959; Wirtz 1968; Alcorn 1984; Johanos *et al.* 1987), but the different types have not been consistently described. Injuries to monk seals have received increased interest recently because they apparently have a detrimental effect on the reproduction and survival of individual seals, which in turn may negatively affect overall population growth and recovery of this endangered species (Gilmartin 1983). Consequently, it is important to describe and quantify the types of wounds to facilitate monitoring of their origin and frequency and to assess their significance to injured individuals as well as to the monk seal population as a whole.

Most injuries noted in the past have been attributed to attacks by sharks (e.g., Kenyon 1973) and to what has been termed "mobbing" behaviour of adult male monk seals (e.g., Alcorn 1984). Shark attack has been thought to be an important cause of mortality (Kenyon 1973). Although sharks have been observed to attack and feed upon monk seals (Balazs and Whittow 1979; Alcorn and Kam 1986), the extent to which shark predation affects the population is unknown. Mobbing behaviour involves many males trying to mate simultaneously with one female or subadult (male or female) seal (Johnson

and Johnson 1981; Johanos and Kam 1986; Johanos *et al.* 1987). During mating, the male mounts the female and bites her to hold his position on her back (Johanos *et al.* 1990). Puncture wounds and abrasions may be inflicted on the back of the female during mating. When more than one male tries to mate simultaneously with one seal, the biting becomes intense and harassment of the seal may continue over several hours, resulting in the formation and subsequent enlargement of open dorsal wounds (Johnson and Johnson 1981). In extreme cases the resulting wound may expose up to two-thirds of the dorsum (Alcorn 1984). Because of the apparent severity of such wounds, and of those inflicted by large sharks, the survival rate of wounded seals may be significantly lowered (Wirtz 1968; Johnson and Johnson 1981; Gilmartin 1983; Alcorn 1984).

In this paper we describe six major categories of injuries observed in two Hawaiian monk seal populations in the northwestern Hawaiian Islands during 1988 and 1989. Because wounds inflicted by adult male seals and by large sharks appear severe enough to affect the survival and reproduction of individuals, we examine the frequency of occurrence of these injuries in 1982–1989, and their possible effect on the monk seal population.

## Study sites and methods

Laysan Island (latitude 25°42′N, longitude 171°44′W; Fig. 1) is a low coral sand island about 2.8 km long and 1.7 km wide, with a hypersaline lake in its center. The island is surrounded by a fringing coral reef varying from 90 to 460 m in width (Ely and Clapp 1973). In 1989, when the entire monk seal population was identified, it consisted of 258 seals (excluding pups). The ratio of adult males to adult females was about 1.6:1 (Honolulu Laboratory, unpublished data).

French Frigate Shoals (FFS, latitude 23°45′N, longitude 166°10′W; Fig. 1) is a coral atoll with a crescent-shaped fringing reef, approximately 32 km long and 9.6 km wide, covering about 363 km$^2$ and containing 12 permanent sand islets, several sandspits that vary in size and location through the year, and one island of volcanic rock (Amerson 1971). The estimated monk seal population at FFS in 1988 was 623 animals (excluding pups). From beach counts, the ratio of adult males to adult females was estimated at 0.6:1 (Gilmartin *et al.* 1993).

We collected injury and census data on Hawaiian monk seals at Laysan Island during 28 February – 21 June 1988 and 28 March – 17 July 1989. At FFS, data were collected during 13 April – 30 August 1988 and 28 March – 3 September 1989. We also analyzed census and injury data collected in 1982–1987 at Laysan Island, and in 1985–1987 at FFS by Honolulu Laboratory personnel as part of an ongoing study of the population dynamics of Hawaiian monk seals.

At Laysan Island, adult and subadult seals were identified by means of numbers applied with commercial bleach (Stone 1984; all years except 1982, 1986, and 1987), distinctive scars, and natural markings. In addition, weaned pups were tagged with plastic Temple Tags (Gilmartin *et al.* 1986) each year beginning in 1983, and adult males were tagged from 1983 through 1988 (Johanos *et al.* 1987; Johanos and Austin 1988; Alcorn and Buelna 1989; Johanos *et al.* 1990). Seals with distinctive marks (e.g., large scars, flipper tags, or natural markings) were easily identified between years, but seals known only by marks applied with bleach were not consistently identified between years. At FFS, individuals were identified, when possible, by means of distinctive scars and natural markings. Temple Tags were applied to weaned pups beginning in 1984. No animals were marked with bleach and adult animals were not tagged during the study period.

Each seal was assigned to a size class on the basis of known age (e.g., nursing pup, weaned pup), reproductive state (adult female with nursing pup), or estimated size (juveniles, subadults, and adults), using criteria described in Stone (1984). The sex of a seal was recorded if seen, or if the seal had been previously identified and its

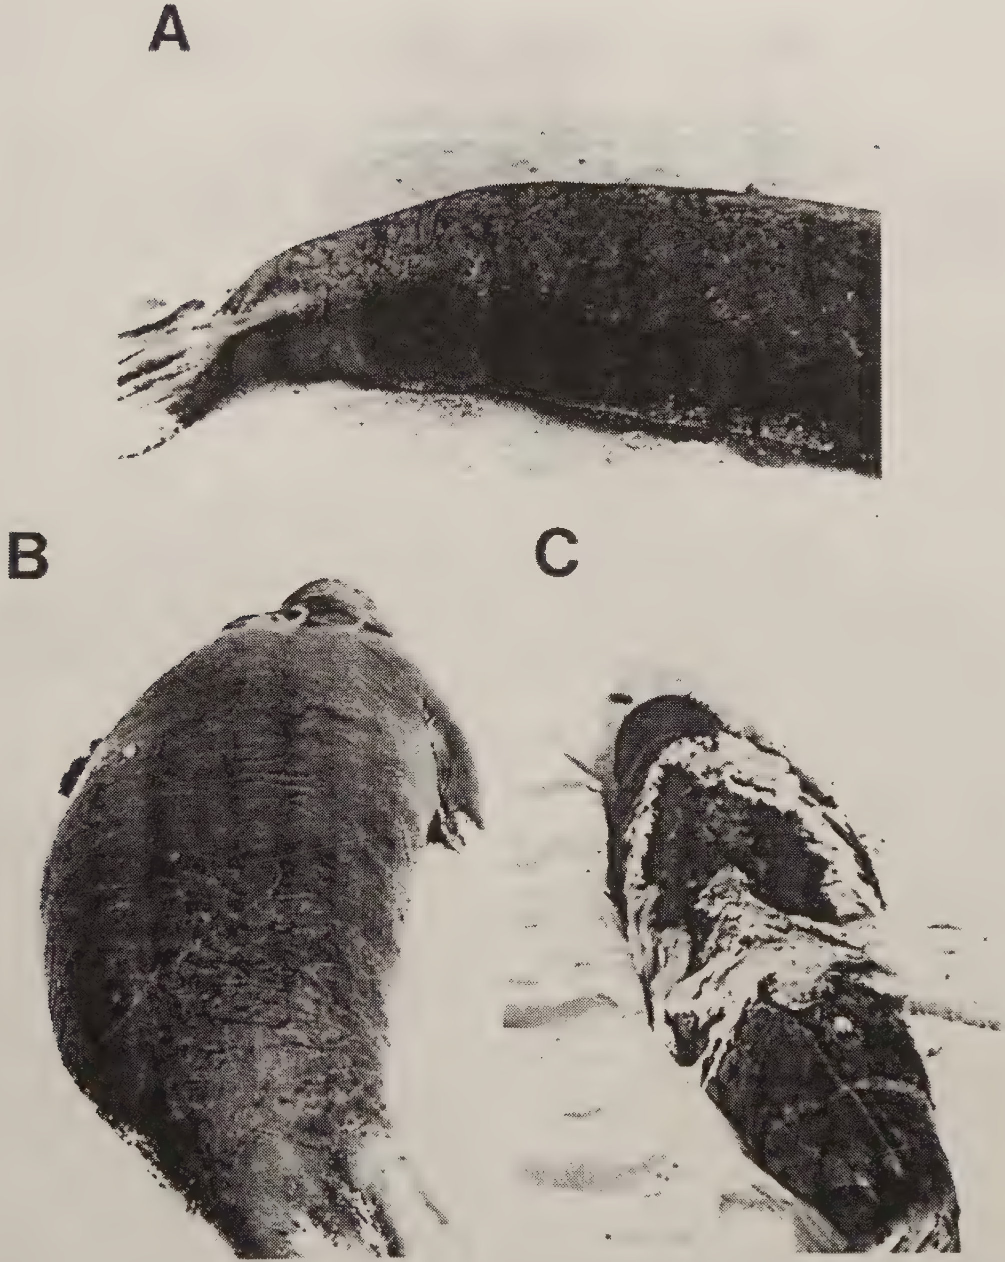

FIG. 2. Typical dorsal abrasions and lacerations (A and B) and gaping open dorsal injury (C) inflicted by adult male seals during mobbing incidents.

sex was known. An adult seal with a nursing pup was always classed as female.

The population composition was determined from daily census data. During censuses, all seals on land (with >50% of the body out of water) were counted as the observer walked around the perimeter of the island. On non-census days, less standardized observations were taken. Slightly different procedures were used at Laysan Island and FFS. At Laysan Island, censuses were conducted every 2–4 d, and took about 2.5 h to complete. Censuses at FFS were conducted every 1–2 weeks over a 2-d period. At islets too small for an

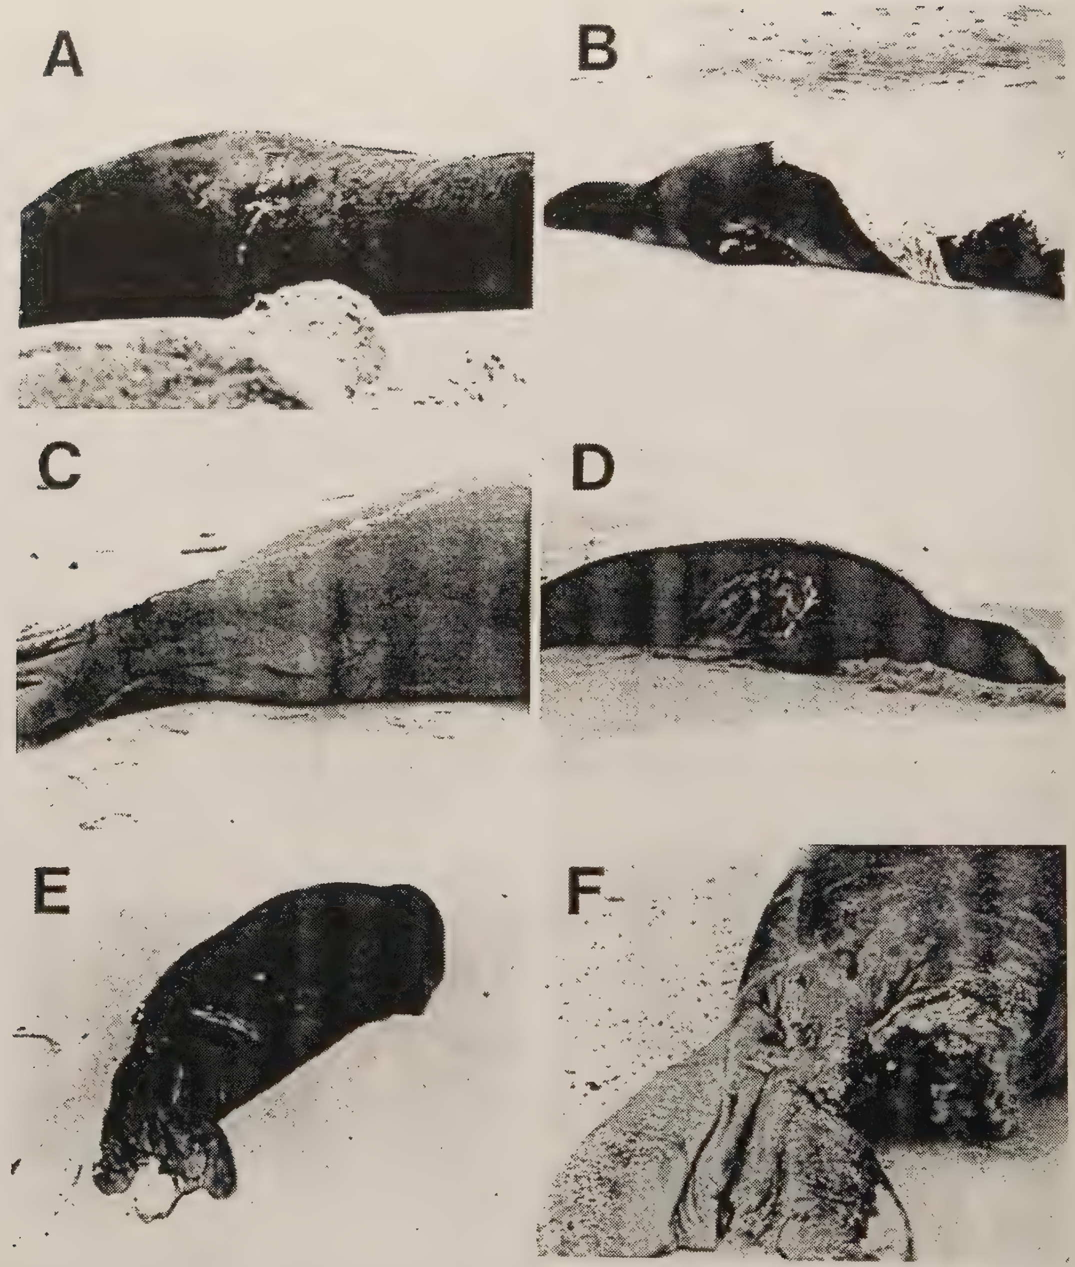

FIG. 3. Seal with a small open dorsal injury (A) and, about 10 days later, with a gaping open dorsal injury (B), both inflicted by adult male monk seals. (C) Seals with lacerations showing the shape of a shark's jaw. (D) A gaping injury showing the shape of a shark's jaw. (E) Fresh lacerations. (F) Seal with a hind flipper amputated.

observer to land without disturbing the seals, animals were counted from the boat.

Injuries were recorded both on census and non-census days. We standardized injury descriptions by grouping injuries into six types, based on physical characteristics: (1) *puncture*: small-diameter (<2 cm) hole, such as that created by a sharp pointed object piercing the skin; (2) *abcess*: a swollen, blister-like area under the skin; (3) *abrasions and lacerations*: scratches or tears in the skin ranging in depth from surface scratches (not breaking the skin) to deep tears in the muscle tissue; (4) *gaping wound*: an open, irregular- or oval-shaped wound

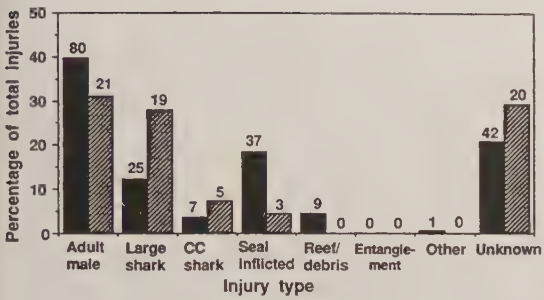

FIG. 4. Relative frequencies of different types of wounds observed on Hawaiian monk seals from April to June of 1988 and 1989 at Laysan Island (solid bars) and French Frigate Shoals (FFS) (hatched bars) in the northwestern Hawaiian Islands. See text for a description of wound types. The number of injuries of each type is indicated above each bar. "CC shark" indicates the cookiecutter shark (*Isistius brasiliensis*).

where flesh was removed; (5) *circular wound*: a wound ranging from a semicircular cut through the skin to a circular wound with flesh removed; (6) *amputation of a limb*: all or part of a limb removed from the body. Injuries recorded in 1988 and 1989 were classified by the observer. We classified injuries recorded by Honolulu Laboratory personnel from 1982 to 1987 by examining drawings and photographs taken at the time of observation. Each injury was used once in the analysis. If an animal was injured more than once during a season and the injuries were from a different source, the two injuries were counted separately.

### *Data analyses*

Only data from 1988 and 1989 were used to examine the frequency of occurrence of injuries from different sources because wounds were recorded more often and more systematically during those years. Data from all years (1982–1989) were used when examining injuries inflicted by adult male seals or by large sharks, as emphasis in data collection from 1982–1987 was placed on monitoring aggressive male behaviour and interactions between sharks and seals (e.g., Alcorn and Buelna 1989).

To minimize seasonal variation in censuses (Gerrodette 1985), we used the average number of seals counted in May and June of 1988 and 1989 as an index of the relative size of the population. To compare the monthly frequencies of occurrence of injuries inflicted by adult male seals and by large sharks between Laysan Island and FFS, we divided the monthly numbers of the two injury types by this index of population size.

To determine if data collected in 1988 and 1989 were similar to those collected in 1982–1987, we compared the two data sets (*G*-test; Sokal and Rohlf 1981). We pooled the data sets where no statistically significant differences were detected. All tests were evaluated at the 0.05 significance level.

## Results

### *Causes of injuries*

The shape of an injury and its location on the seal's body were often indicative of its origin. Six characteristic types of injuries, based on the cause of the wound, were observed.

### *Injuries inflicted by adult male monk seals during mating attempts*

Wounds inflicted by adult males during mating attempts consisted of abrasions on the dorsum of the injured seal, occasionally extending to its sides. The scratches were caused by an adult male attempting to hold the seal with its teeth and foreflippers while mounting it (Figs. 2A, 2B). Often the dorsum of the injured seal was dark because of subcutaneous hemorrhage (Alcorn 1984) and fluids leaching from the abrasions. Some seals also sustained more severe gaping wounds, usually in the midbody to posterior dorsal area. These gaping wounds ranged from small (ca. 2 cm diameter; Fig. 3A) to large open areas covering up to two-thirds of the injured animal's back (Figs. 2C, 3B; Alcorn 1984). In many cases the injured seal was observed with one or more adult males.

Mating injuries inflicted by adult males were the most frequently observed of all injuries at both Laysan Island and FFS (Fig. 4). These injuries were observed earlier in the year (April and May; Fig. 5), and the number of injuries (per 100 seals counted) inflicted was much higher at Laysan Island than at FFS. In June and July the rates from both areas were similar. At both Laysan Island and FFS the distribution of injuries inflicted by adult male seals over the size and sex classes of

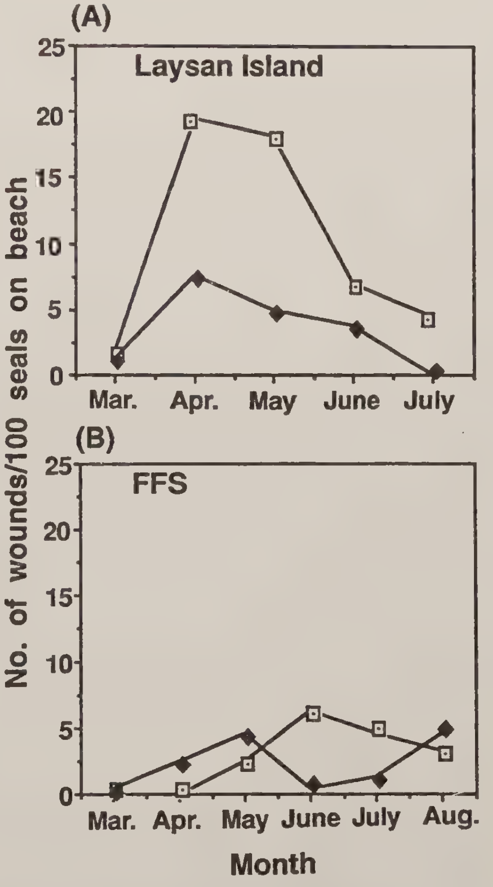

FIG. 5. Rate of wounding of Hawaiian monk seals by other adult male monk seals (⊡) and large sharks (♦) at Laysan Island (A) and French Frigate Shoals (B) in the northwestern Hawaiian Islands, 1988 and 1989. Seals of all size and sex classes are included.

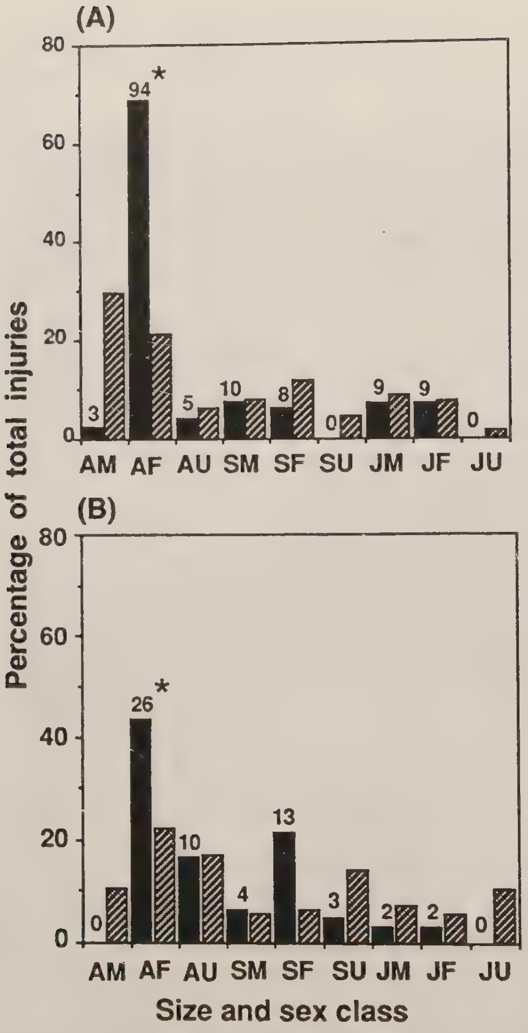

FIG. 6. Observed (solid bars) and expected (hatched bars) proportions of injuries inflicted by adult male Hawaiian monk seals on seals of different size and sex classes at Laysan Island (A) and French Frigate Shoals (B) in the northwestern Hawaiian Islands, 1982–1989. Expected frequencies are based on mean censuses in May and June of 1982–1989. The number of injuries in each class is indicated above each bar. AM, adult male; AF, adult female; AU, adult of unknown sex; SM, subadult male; SF, subadult female; SU, subadult of unknown sex; JM, juvenile male; JF, juvenile female; JU, juvenile of unknown sex. An asterisk indicates a significant difference between expected and observed proportions in a class.

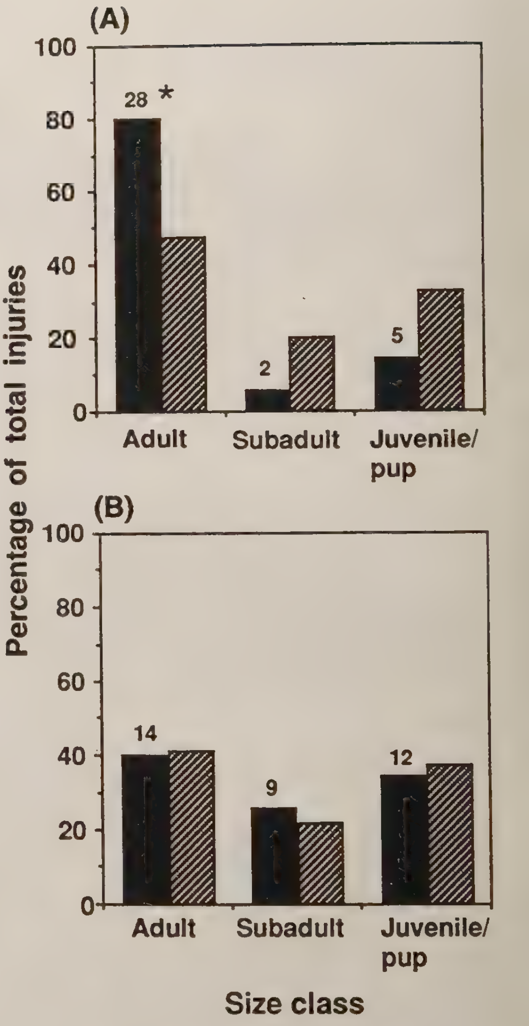

FIG. 7. Observed (solid bars) and expected (hatched bars) injuries inflicted by large sharks on Hawaiian monk seals of different size-classes at Laysan Island (A) and French Frigate Shoals (B) in the northwestern Hawaiian Islands, 1982–1989. Expected frequencies are based on mean censuses in May and June of 1982–1989. The number of injuries in each class is indicated above each bar. An asterisk indicates a significant difference between expected and observed proportions in a class.

monk seals was not directly proportional to the number of seals in each size and sex class counted on the beach (*G*-test with Williams' correction; Sokal and Rohlf 1981; Laysan: $G = 172.65$, df = 8, $p < 0.005$, Fig. 6A; FFS: $G = 53.38$, df = 8, $p < 0.005$, Fig. 6B; injured animals of unknown sex were excluded from the analysis). Significantly more adult females were injured at both Laysan Island and FFS than expected from their relative numbers in the population (Laysan: $G = 52.76$, df = 1, $p < 0.005$; FFS: $G = 7.48$, df = 1, $p < 0.01$). At FFS, the distribution of injuries inflicted by adult males over size and sex classes should be interpreted conservatively because adult females were more likely to be identified than adult males, therefore the expected numbers of adult males and females may have been biased in favour of females. Even so, the proportion of mating injuries inflicted by adult males on adult and subadult females was much higher than on any of the other size classes (Fig. 6B).

*Injuries inflicted by other seals during aggressive interactions*

Seals inflicted abrasions and bite wounds on each other during jousting interactions, where two seals lunge at one another with open mouths and occasionally bite each other (Kenyon and Rice 1959) around the head, neck, and hind flippers. Injuries due to aggressive interactions accounted for 18.4% of injuries seen at Laysan Island but only 4.4% of injuries at FFS. Of 37 injuries of this type at Laysan Island, adult male seals were injured significantly more often than seals of other size and sex classes ($n = 27$; $G = 23.52$, df = 1, $p < 0.005$). At FFS, two of the three seal-inflicted injuries were sustained by adult males.

*Injuries inflicted by large sharks*

Injuries inflicted by large sharks included shallow punctures in the skin, deep lacerations, gaping wounds, and amputated limbs (Figs. 3C–3F). The characteristic crescent shape of these wounds reflected the shape of a shark's jaw (Figs. 3C, 3D). Large sharks inflicted 12.4% of injuries observed at Laysan Island and 27.9% of those seen at FFS (Fig. 4).

The number of injuries inflicted by large sharks observed (per 100 seals) at Laysan Island was highest from April through June (Fig. 5). At FFS over the same period, the rate of shark-inflicted injuries observed per 100 seals varied, but was lower than at Laysan Island in most years.

At Laysan Island, injuries inflicted by large sharks were observed significantly more often on adult seals than on subadults and juveniles ($G = 15.83$, df = 2, $p < 0.005$, Fig. 7A), and were observed significantly more frequently on adult males than on seals of other size classes ($G = 15.95$, df = 1, $p < 0.005$). At FFS, the distribution of large shark inflicted injuries was independent of size class ($G = 0.369$, df = 2, $p > 0.9$; Fig. 7B). Adult males did not sustain a significantly greater proportion of injuries than expected ($G = 1.67$, df = 1, $0.5 < p < 0.1$).

*Injuries inflicted by cookiecutter sharks (*Isistius brasiliensis*)*

Injuries inflicted by cookiecutter sharks included circular or semicircular cuts through the skin or round, open wounds 3–7 cm in diameter and 1–2 cm in depth, sometimes with a circular plug of skin and tissue attached to the edge of the wound (Fig. 8A). These injuries were seen with greater frequency at Laysan Island than at FFS (Fig. 4).

*Injuries due to contact with coral reef or debris*

A seal sustained abrasions, close together and parallel to each other (Fig. 8B), and single scratches when it scraped past a coral reef or sharp pieces of metal or glass debris. These injuries were minor and not observed frequently at FFS (Fig. 4).

*Injuries due to entanglement in netting*

Injuries caused by entanglement in netting or marine debris were deep, linear wounds, usually around the neck of the animal (Fig. 8C).

*Other injuries and unknown causes*

Injuries due to known but infrequently seen causes were classed as "other." Any injuries for which the cause was uncertain were classed as "unknown." At both Laysan Island

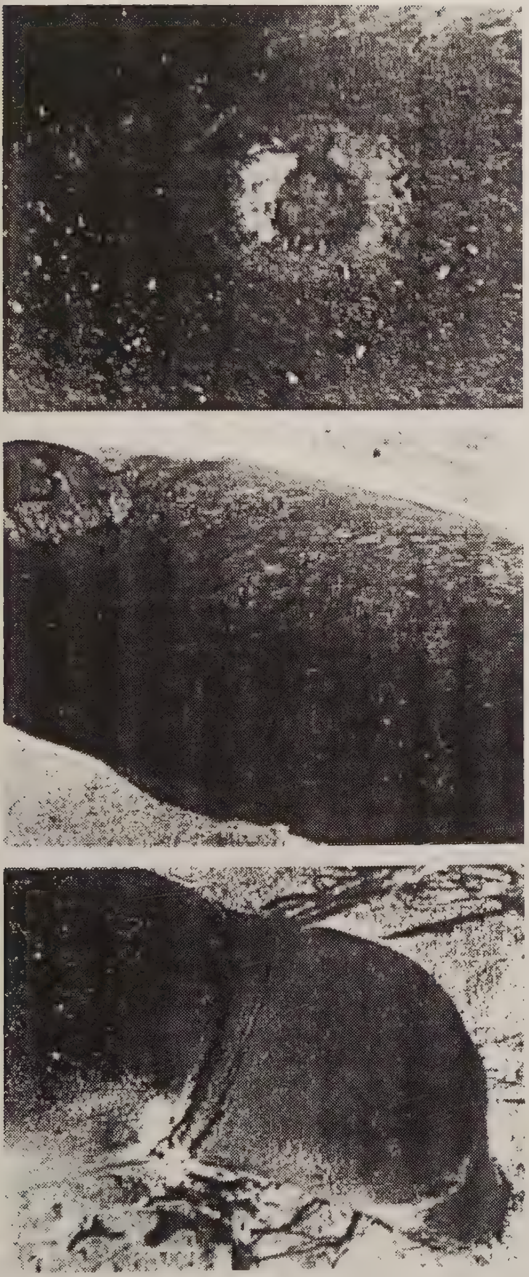

FIG. 8. Injuries observed on Hawaiian monk seals. (A) Round, crater-shaped wound caused by the cookiecutter shark (*Isistius brasiliensis*). (B) Parallel abrasions, close together, caused by contact with coral reef or debris. (C) Deep linear injury around neck of seal caused by a fishing net.

and FFS the proportion of injuries of unknown origin was high (20.9% at Laysan Island; 29.4% at FFS).

## Discussion

### *Injuries inflicted by adult males during mating incidents*

Mating injuries inflicted by adult males are likely to have a negative impact on the monk seal population because of their frequency (Fig. 4), severity (e.g., Figs. 2C, 3B), and occurrence mostly on female seals (Fig. 6; Hiruki *et al.*[2]). Although comparisons between Laysan Island and FFS should be interpreted cautiously, given the differences in frequency and methodology of seal counts at the two locations, the disparity in timing and rate of occurrence of adult male inflicted injuries is striking. Adult male inflicted injuries were observed earlier in the year and with 3–4 times greater incidence per 100 seals at Laysan Island than at FFS (Fig. 5). The higher frequency of such wounds at Laysan Island, combined with a small adult female population and increased female mortality due to injuries (Hiruki *et al.* 1993; Hiruki *et al.*[2]), suggest that wounding is likely to have a greater impact on the monk seal population at Laysan Island than on the population at FFS (Hiruki *et al.*[2]).

In other species, males also inflict injuries on females during courtship and mating, though the wounds may not be fatal. Male crabeater seals (*Lobodon carcinophagus*) usually bite the female on the neck while attempting to mount her (Siniff *et al.* 1979), resulting in considerable light wounding and superficial bleeding. Male southern elephant seals (*Mirounga leonina*) commonly inflict wounds on the female's neck during mating (McCann 1982). Male sea otters (*Enhydra lutris*) apparently infict wounds on the female during mating when the male takes a hold on the female's nose with his teeth (Foott 1970). Hatler (1972) found more serious wounds in a wild population of mink (*Mustela vison*) on Vancouver Island, where nearly every female mink observed during the mating season had extensive neck wounds.

Simultaneous pursuit of, and mating attempts with, a single female by many males, sometimes leading to injury or death of the female, is known in species other than the Hawaiian monk seal. Harassment of individual females by a group of males has been recorded for Australian sea lions (*Neophoca cinerea*; Marlow 1975) and southern sea lions (*Otario byronia*; Campagna and Le Boeuf 1988), where groups of subordinate males harass females as they arrive at or leave the breeding colony. Female northern elephant seals (*Mirounga angustirostris*), when harassed by groups of subordinate males, may sustain injuries serious enough to be fatal during mating (Le Boeuf and Mesnick 1990; Mesnick and Le Boeuf 1991). Groups of male manatees (*Trichechus manatus*) often pursue a single estrous female and attempt to copulate with her (Hartman 1979). Female dugongs (*Dugong dugon*) are frequently scarred by males attempting to mate with them (Anderson and Birtles 1978) and are sometimes mounted by several males until the female "appears very tired" (Preen 1989). A female mink can die from neck injuries that become enlarged when several males mate with her over a short period of time (Hatler 1972). In many species of waterfowl, forced extra-pair copulatory behaviour, in which one or several males pursue and attempt to mate with one female, has been widely documented (e.g., Titman and Lowther 1975; Bailey *et al.* 1978), and the female is occasionally killed during these incidents (McKinney *et al.* 1983). Female white-fronted bee-eaters (*Merops bullockoides*) are often chased by as many as 12 males during forced copulation attempts (Emlen and Wrege 1986). Female toads (*Bufo bufo*) and wood frogs (*Rana sylvatica*) involved in mating struggles in areas of high density may be drowned at the center of a ball of struggling males (Howard 1980; Arak 1983). Thus, the phenomenon of severe injuries inflicted on females by many males during the mating season is not unique to Hawaiian monk seals but is nevertheless important if the number of female seals is reduced as a result of mortality caused by these wounds, such as in the monk seal population at Laysan Island (Hiruki *et al.* 1993; Hiruki *et al.*, see footnote 2).

### *Injuries inflicted by seals during aggressive interactions*

The higher rate of injuries inflicted by seals during jousts or aggressive interactions at Laysan Island during 1988 and 1989 (Fig. 4) may indicate a higher level of intrasexual competition and aggressive behaviour between males at Laysan Island than at FFS. Males of many species often wound each other when competing for females (e.g., Weddell seals, *Leptonychotes weddelli*: Smith 1966; northern elephant seals: Le Boeuf 1974; Cox 1981; crabeater seals: Siniff *et al.* 1979; red deer, *Cervus elaphus*: Clutton-Brock *et al.* 1979; mule deer, *Odocoileus hemionus*, and white-tailed deer, *O. virginianus*: Geist 1986). In the context of males competing for females, other factors that may promote a higher level of aggressive behaviour at Laysan Island include its smaller size in comparison with FFS (Fig. 1), and the adult sex ratio at Laysan Island, which is skewed towards males. Deutsch (1985) found that Hawaiian monk seal males compete in two ways, as defined by Barash (1978): scramble competition, where a male searches for receptive females, and contest competition, where a male defends a female against intruding males. At Laysan Island, the distance a male must travel to find a receptive female is less than at FFS, suggesting that males at Laysan Island encounter receptive females, or males defending females, more frequently than at FFS. In addition, the greater number of males per female in the adult population at Laysan Island than at FFS implies that there are more contests between males for each female at Laysan Island. Thus, male monk seals at Laysan Island appear more likely than males at FFS to be involved in contests and aggressive interactions.

### *Injuries inflicted by large sharks*

Of the sharks commonly seen in the northwestern Hawaiian Islands (NWHI), tiger sharks (*Galeocerdo cuvier*) have the most potential to affect the monk seal population, as they are known to attack and eat monk seals (Taylor and Naftel 1978; Balazs and Whittow 1979; Alcorn and Kam 1986; B. L. Becker and L. M. Hiruki, personal observations). Hammerhead sharks (*Sphyrna lewini*) and mako sharks (*Isurus paucus*) have also been observed in the NWHI (Rice 1960), but there is no evidence that they attack monk seals. Although gray reef sharks (*Carcharhinus amblyrhynchos*) have not been observed to attack monk seals, they may be present when tiger sharks attack monk seals (Alcorn and Kam 1986).

---

[2] L. M. Hiruki, I. Stirling, W. G. Gilmartin, B. L. Becker, and T. C. Johanos. Effects of wounding on monk seal (*Monachus schauinslandi*) population dynamics. Manuscript in preparation.

At Laysan Island, the larger proportion of injuries inflicted by sharks on adult monk seals than on seals of other size classes (Fig. 7A) may indicate either that juveniles are not injured by large sharks or, more likely, that juveniles are less likely to survive attacks by large sharks. Immature seals are generally considered to be more vulnerable to shark attack than adult seals (Le Boeuf *et al.* 1982; Brodie and Beck 1983; Ainley *et al.* 1985), perhaps because their lack of experience or smaller size makes them easier prey for sharks (Ainley *et al.* 1985). Both juvenile gray seals (*Halichoeurus grypus*; Brodie and Beck 1983) and juvenile bottlenose dolphins (*Tursiops truncatus*; Cockcroft *et al.* 1989) are relatively free of the scars typical of shark attacks, suggesting that they rarely escape when attacked by sharks. The predominance of young dolphin remains in shark stomachs also indicates that juveniles may be more vulnerable to shark attack than seals of other size classes (Cockcroft *et al.* 1989). If juvenile monk seals are less likely than adults to survive a shark attack, the effect of shark predation on juvenile seals may be greater than is indicated in Fig. 7.

Among adult seals, injuries inflicted by large sharks were observed more often on males than on females. Most of the injuries inflicted by large sharks were observed in April and May (Fig. 5), coinciding with the peak of the pupping season (Kenyon and Rice 1959; Kenyon 1981); however, as our observations did not extend past August, we have no data on the frequency of shark-inflicted injuries outside the pupping season. Nursing females stay on land or in shallow water until their pups are weaned (Kenyon and Rice 1959). During the same period, adult males spend most of their time in the water patrolling the shore and searching for receptive females. Thus, adult males may be more vulnerable than adult females to injury from sharks during the pupping season.

The decrease in the rate of wounding by sharks at both Laysan Island and FFS in June and July (Fig. 5) may have been due to tiger sharks shifting their focus to albatross chicks (*Diomedia* spp.). Tiger sharks begin to swim near the shore of several islands in the NWHI in mid-June, apparently to prey on albatross fledglings as they land in the water to rest between flights (Rice 1960; Johnson and Johnson 1981; W. R. Strong, personal communication). The seasonal predation on albatross chicks by tiger sharks in the NWHI may thus influence the frequency of shark attacks on monk seals (Rice 1960; Fisher 1975; W. R. Strong, personal communication).

### *Injuries inflicted by cookiecutter sharks*

The cookiecutter shark is a small squaloid shark, 14–50 cm long, that inhabits the deep (85–3500 m) water of tropical and subtropical areas of the Atlantic, Pacific, and Indian oceans (Castro 1983; Compagno 1984). Jones (1971) speculated that the bioluminescent pattern of the cookiecutter shark mimics that of a squid, and in doing so attracts squidophagous predators. Le Boeuf *et al.* (1987) view this as a likely explanation of how the cookiecutter shark attacks northern elephant seals. It is probable that Hawaiian monk seals are attacked in a similar way while feeding.

### *Interactions between wounding by adult male monk seals and by sharks*

At Laysan Island the rates of wounding by both adult male seals and large sharks were relatively high in April and May (Fig. 5). The overlap in peak periods of adult male inflicted mating injuries in shark-inflicted injuries may be related: body fluids leaching from a seal's injuries probably attract sharks, or a wounded seal may be less vigilant and less mobile in the water, both of which could increase its vulnerability to shark attack. Further, activity in the water can attract sharks; tiger sharks have been seen patrolling underneath aquatic mobbing incidents (Johanos and Austin 1988) and have subsequently attacked injured female seals (Alcorn and Kam 1986) as well as males involved in mobbing incidents (Johanos and Austin 1988). The combination of wounding by adult male monk seals and by sharks may thus increase the mortality rate for seals.

At FFS, the peak period of adult male inflicted injuries (June–July) did not overlap with the peak period of shark-inflicted injuries (April–May). This may indicate that sharks have less opportunity at FFS than at Laysan Island to attack seals involved in mobbing incidents. Alternatively, large sharks may be present at FFS later in the year, when fewer mating injuries occur, or their attacks upon injured seals at FFS may be rarely documented.

Of the six types of injuries observed on Hawaiian monk seals, those with the most potential to affect the population are caused by adult male monk seals during mating attempts and by large sharks. Adult male inflicted mating injuries were seen more often than other types of injuries and were inflicted mostly on females; shark-inflicted injuries may increase the mortality rate for such injured females. These two types of injuries are significant to the extent that they could negatively affect female survival and productivity, both of which are critical to population growth (Eberhardt 1985) of this endangered species.

## Acknowledgments

We extend our thanks to the Honolulu Laboratory biologists and volunteers who helped to collect data: D. Alcorn, M. Brainard, R. Brainard, B. Choy, M. Craig, R. Forsyth, T. Gerrodette, J. Henderson, L. Honigman, and R. Westlake. We greatly appreciated the support of the U.S. Fish and Wildlife Service, Hawaiian Islands National Wildlife Refuge staff; the NMFS SWFSC Honolulu Laboratory; the Canadian Wildlife Service; and the captain, officers, and crew of the NOAA ship *Townsend Cromwell* and the fishing vessel *Feresa*. J. O. Murie, S. J. Hannon, L. M. Fedigan, S. A. Boutin, T. Gerrodette, J. F. Hare, T. J. Ragen, and two anonymous reviewers commented constructively on earlier drafts of the manuscript. R. Mandryk and J. Przysiezniak assisted with the figures. This study was done in partial fulfillment of the requirements for a Master's degree awarded to L. M. Hiruki by the University of Alberta, and was funded in part by a Natural Sciences and Engineering Research Council of Canada postgraduate scholarship and a University of Alberta Graduate Faculty Fellowship to L. M. Hiruki and by a World Wildlife Fund grant to I. Stirling.

HIRUKI, L. M., STIRLING, I., GILMARTIN, W. G., JOHANOS, T. C., and BECKER, B. L. 1993. Significance of wounding to female reproductive success in Hawaiian monk seals (*Monachus schauinslandi*) at Laysan Island. Can. J. Zool. **71**: 469–474.

We studied reproductive rate, length of lactation period, pup survival, and mortality of injured and uninjured female Hawaiian monk seals (*Monachus schauinslandi*) on Laysan Island, northwestern Hawaiian Islands, in 1983–1989. The severity and timing of nonfatal injuries were influential in determining their effect on female reproductive success. There was a tendency towards a shorter mean lactation period and lower survival rate of pups for females with major injuries than for uninjured females. Females with minor injuries were similar to uninjured females in terms of reproductive rate, length of lactation, and pup survival. For females injured shortly before the birth of their pup or during lactation, pup survival was lower than for uninjured females, whereas for females injured during the year prior to pupping, measures of reproductive success were not significantly different from those for uninjured females. Immature (aged 4–8 years) females entering the reproductive population were injured by adult male seals significantly more often than females aged 0–3 years, but at a similar rate to adult females. The major effect of injuries on female reproductive success is an increase in female mortality: 87.5% of the adult females ($n = 16$) that died on Laysan Island in 1983–1989 sustained injuries from adult male seals.

HIRUKI, L. M., STIRLING, I., GILMARTIN, W. G., JOHANOS, T. C., et BECKER, B. L. 1993. Significance of wounding to female reproductive success in Hawaiian monk seals (*Monachus schauinslandi*) at Laysan Island. Can. J. Zool. **71** : 469–474.

Nous avons étudié le taux de reproduction, la durée de l'allaitement, la survie des petits et la mortalité des femelles blessées et saines dans une population de Phoques-moines (*Monachus schauinslandi*) sur l'île Laysan dans le nord-ouest de l'Archipel hawaïen de 1983 à 1989. L'effet des blessures non mortelles sur le succès de la reproduction des femelles dépendait de l'importance de la blessure et de la période où elle se produisait. Les femelles portant des blessures graves avaient tendance à allaiter moins longtemps en moyenne que les femelles saines et leurs petits avaient un taux de survie moindre. Les femelles n'ayant que des blessures superficielles avaient un taux de reproduction, une période d'allaitement et un taux de survie de leurs petits qui ne différaient pas de ceux des femelles saines. Les femelles blessées peu avant la mise bas ou durant la période d'allaitement avaient plus tendance à perdre leurs petits que les femelles saines; toutefois, une blessure reçue un an avant la mise bas n'affectait pas de façon significative le taux de reproduction. Les femelles immatures, âgées de 4–8 ans, qui commençaient leur vie reproductive, recevaient plus de blessures de la part des mâles adultes que les femelles âgées seulement de 0–3 ans, mais tout autant que les femelles adultes. L'effet principal des blessures sur la reproduction est lié à la mortalité des femelles : 87,5% des femelles adultes mortes sur l'île Laysan en 1983–1989 ($n = 16$) portaient des blessures causées par des mâles adultes.

[Traduit par la rédaction]

## Introduction

In recent years, efforts to identify factors contributing to a decrease in the survival and productivity of Hawaiian monk seals (*Monachus schauinslandi*) have increased as part of an overall recovery plan (Gilmartin 1983, 1988). Counts of monk seals have declined from about 1000 in 1959 to approximately 580 in 1987 (Johnson *et al.* 1982; Gilmartin 1988). In this situation, even a slight decrease in female survival or productivity could have a significant negative impact on population dynamics, as the net growth of a pinniped population is dependent on, and most sensitive to, female survival and, to a lesser extent, female reproductive success (Eberhardt and Siniff 1977; Eberhardt 1985). Wounds inflicted on adult females by males during mating attempts are the most common type of injury observed in monk seals (Hiruki *et al.* 1993). Consequently, the occurrence of such injuries and their potential effect on reproductive success have become matters of concern (Gilmartin 1983).

Female reproductive success (i.e., the number of viable offspring produced by a female during her lifetime) can be subdivided into several components, such as survival of the female to breeding age, reproductive life-span, and the production and survival of offspring (Clutton-Brock 1988), all of which

---

Printed in Canada / Imprimé au Canada

could be influenced by injuries. In long-lived animals such as monk seals that can reproduce until at least 25 years of age (Johanos *et al.* 1990), longevity is a significant component of the lifetime reproductive success of females (Le Boeuf and Reiter 1988; Thomas and Coulson 1988), particularly if only one offspring is produced per year. If injuries increase the mortality of female monk seals, their lifetime productivity will be reduced.

Injuries to adult female monk seals could affect the production of pups in several ways. A wounded female may be less likely to breed because her resources are needed to ensure her own survival, or if she does breed, her pup may be aborted. Injured female northern elephant seals (*Mirounga angustirostris*) did not copulate in the year that they were injured and thus did not pup in the year following the injury (Le Boeuf *et al.* 1982).

The survival of pups born to wounded females may also be reduced. If an injured female has a pup, the amount of energy she is able to invest during the nursing period may be less than that of an uninjured female. Energy stored for lactation or for development of her pup might be redirected towards recovery from the injury (Ainley *et al.* 1981). Similarly, a pregnant female recovering from an injury might not be in as good condition at parturition as an uninjured female. Female Hawaiian monk seals fast during the entire nursing period (Kenyon and Rice 1959), as do most other phocid seals (e.g., northern elephant seals (Riedman and Ortiz 1979); harp seals, *Phoca groenlandica* (Lavigne *et al.* 1982); grey seals, *Halichoerus grypus* (Anderson and Fedak 1987)). If a female monk seal is in poor condition when her pup is born, she may be more likely to have a smaller pup or to wean her pup prematurely, because she is not feeding and cannot replenish her energy stores during lactation. A low weight at weaning may reduce the pup's probability of survival through its first year of life.

This paper examines the influence of injuries on four components of female reproductive success (reproductive rate, maternal investment, survival of pups, and mortality of adult females) to test the hypothesis that injuries inflicted by adult males negatively affect survival and reproduction. We also evaluate the significance of injury to the recruitment of young females into the breeding population.

## Methods

The reproductive histories and injuries of female Hawaiian monk seals were analyzed from data collected at Laysan Island, a low coral and sand island located northwest of the main Hawaiian Islands (latitude 25°42′N, longitude 171°44′W), during 24 April – 21 July 1983, 30 March – 6 August 1984, 6 March – 1 December 1985, 1 May – 4 August 1986, 6 April – 22 July 1987, 28 February – 21 June 1988, and 30 March – 14 July 1989. Females were identified by temporary marks applied with commercial bleach at the beginning of the field season, by natural markings or scars, or by flipper tags applied in previous years (e.g., Stone 1984; Hiruki *et al.* 1993). For each female with a pup, the date of parturition, weaning date, and the pup's permanent identification number were also recorded. Pups were tagged after they had been weaned (Johanos *et al.* 1987; Johanos and Austin 1988; Alcorn and Buelna 1989; Johanos *et al.* 1990). Data recorded for each injured female included identification number, size class, location of the seal, and description of the injury, as detailed in Hiruki *et al.* (1993).

Female monk seals were classified as adult or immature on the basis of estimated age. Because reproductive success might be affected by age rather than injury status, seals that matured during the study period were excluded from the analysis of reproductive success. Adults were seals classed as being of breeding size in 1983, according to their length, girth, pelage appearance, and scarring (Stone 1984), or seals that had a pup in 1983 or earlier. Immatures were seals seen as juveniles or subadults in 1983 or 1984, or seals that were born in 1983 or later.

To evaluate the impact of injuries on reproductive success, adult female monk seals were divided into three categories in each year: *uninjured*: females that did not sustain any injuries prior to parturition or in the previous year; *currently injured*: females injured during the current year, before parturition or while still nursing the pup; and *previously injured*: females injured in the previous year, usually after weaning the pup of that year. The last category also included females that were injured in the previous year and were not observed with a pup.

Injuries were classified as minor or major. Minor wounds were circular wounds inflicted by cookiecutter sharks (*Isistius brasiliensis*), wounds inflicted by seals in jousting incidents, or those inflicted by the seal contacting a coral reef or debris (Hiruki *et al.* 1993). Major wounds were dorsal lacerations or gaping wounds inflicted by adult male seals during mating incidents or injuries caused by large sharks (described in Hiruki *et al.* 1993). Some of the wounds inflicted by adult males did not appear to be severe externally (e.g., Fig. 2A, 2B, Hiruki *et al.* 1993), but were classified as major because superficially minor abrasions and lacerations may mask significant subcutaneous damage (Johanos and Austin 1988), and some females die after sustaining seemingly minor wounds from adult male monk seals (Johanos *et al.* 1990; T. C. Johanos, B. L. Becker, and L. M. Hiruki, personal observations).

The reproductive rate, defined as the proportion of females that have a pup in a particular year, of uninjured females was compared with that of females injured in the previous year. The currently injured females were excluded from the analysis of reproductive rate because, by definition, they all had pups.

The parental investment period (the number of days that a female nurses and defends her pup) was calculated from the birth and weaning dates of each pup. If a range of dates was recorded for birth or weaning (e.g., 1–3 March), the last day in the range (3 March) was used to calculate the parental investment period. The lengths of completed parental investment periods of currently and previously injured females were compared, as were those of injured and uninjured females. If a female's parental investment period was cut short because her pup died or because she lost her pup to another female and did not gain another (Johnson and Johnson 1978; Boness 1990), it was excluded from the analysis, so that only complete nursing periods were considered. Females with major and minor injuries were compared independently with uninjured females to assess the effect of severity of injury on parental investment.

Pup survivorship was measured in two ways: the proportion of pups alive at the end of the nursing period and the proportion of pups alive after their first year. The survivorship of the pups of currently injured females and those of previously injured females was compared, and each was compared independently with pups of uninjured females. Pups of females with major and minor injuries were compared independently with pups of uninjured females.

The reproductive histories of all permanently identified adult female seals were examined in relation to the number of major injuries sustained per year in 1988 and 1989. The distribution of major injuries within years (number of injuries per year for each seal) was compared with a Poisson distribution to determine whether some females received a disproportionate fraction of the injuries. The number of identified female seals that died or disappeared from Laysan Island during 1983–1989 was examined to determine how many were known to have been injured by adult males.

Immature seals were divided into two classes, based on their reproductive maturity and age in 1988 and 1989. Seals aged 0–3 years were classed as prereproductive. This classification is based on 5 years being the youngest observed age of first reproduction for Hawaiian monk seals (Johanos *et al.* 1990); hence, the minimum age of first estrus appears to be 4 years, since female monk seals mate

TABLE 1. Power of tests used to compare components of reproductive success between injured and uninjured female Hawaiian monk seals at Laysan Island, northwestern Hawaiian Islands, 1983–1989, and the sample size required to determine a significant difference between the observed proportions when the power of the test = 0.80 ($\alpha$ = 0.05; one-tailed test)

| Comparison | Test statistic | Power of test | Sample size required |
|---|---|---|---|
| Reproductive rate | | | |
| Major vs. uninjured | $G = 0.599$ | 0.19 | 783 |
| Minor vs. uninjured | $G = 0.024$ | 0.10 | 5601 |
| Parental investment | | | |
| Major vs. uninjured | $t = 0.981$ | 0.31 | 49 |
| Minor vs. uninjured | $t = 0.723$ | 0.17 | 260 |
| Survival to weaning | | | |
| Injured vs. uninjured | $G = 5.53$ | 0.82 | 137 |
| Survival through first year | | | |
| Major | | | |
| Current vs. uninjured | $G = 2.92$ | 0.30 | 44 |
| Previous vs. uninjured | $G = 0.002$ | 0.07 | 2953 |
| Pooled vs. uninjured | $G = 1.01$ | 0.1 | 1043 |
| Minor | | | |
| Pooled vs. uninjured | $G = 2.56$ | 0.40 | 138 |

the year before they give birth. Seals aged 4–8 years were classed as transitional, because they were starting to enter the reproductive cohort.

To determine the age-class of immature females injured most frequently by adult males, the proportions in the prereproductive (aged 0–3 years) and transitional (aged 4–8 years) classes of immature seals injured by adult males in 1988 and 1989 were compared.

For comparing two proportions, a 2 × 2 $G$-test with the Williams correction was used (Sokal and Rohlf 1981). Because of the small size of the samples tested, the power of the tests comparing injured and uninjured females was calculated. Also calculated was the sample size needed to be 80% certain of detecting a significant difference between two samples (Casagrande *et al.* 1978; Sokal and Rohlf 1981).

## Results

Data were available on 55 individually identified adult female seals and 10 untagged and 99 tagged immature female seals. Thirteen adult and 2 untagged immature female seals were identified in all years from 1983 through 1989. Only partial records were available for the remaining 42 adult and 8 untagged immature females. All tagged animals were easily identifiable between years; seals identified only by means of minor scars or marks applied with bleach were not consistently identified between years.

### *Power of tests*

The power of most tests used to examine the differences between injured and uninjured females was low (Table 1). Given the proportions compared, the sample sizes required to detect a significant difference between injured and uninjured females were substantial.

### *Reproductive rate and pup survivorship*

No effect due to severity of injury on the reproductive rate of females injured in the previous year was detected (Table 2). The reproductive rates of females with major injuries ($n = 25$; $G = 0.599$, df = 1, $p = 0.474$) and those with minor injuries ($n = 7$; $G = 0.024$, df = 1, $p = 0.892$) were similar to that of uninjured females ($n = 201$).

Of the six pups that died prior to weaning, two had uninjured mothers, two had mothers with a major injury, and two had mothers with a minor injury. No significant difference was detected in survivorship to weaning of pups of females with major injuries, currently ($n = 7$) and previously ($n = 13$; $G = 0.25$, df = 1, $p = 0.687$). Survival to weaning was similar for pups of females with major injuries ($n = 18/20$) and those with minor injuries ($n = 9/11$; $G = 0.361$, df = 1, $p = 0.585$). When the major and minor injury classes were pooled, pup survival to weaning ($n = 27/31$) was significantly lower than that of pups of uninjured females ($n = 119/121$; $G = 5.53$, df = 1, $p = 0.027$).

Survival through the first year of life did not differ significantly for pups of females with major injuries currently ($n = 7$) and previously ($n = 13$; $G = 1.98$, df = 1, $p = 0.229$, Table 2). Pups of currently injured females had slightly lower survival than pups of uninjured females ($n = 121$; $G = 2.92$, df = 1, $p = 0.091$), though the difference was not statistically significant. Pups of females previously with major injuries had survivorship similar to pups of uninjured females ($G = 0.002$, df = 1, $p = 0.965$). Survivorship of pups of injured females (currently and previously injured classes pooled) did not differ significantly from that of pups of uninjured females ($G = 1.01$, df = 1, $p = 0.401$).

Survival through the first year was similar for pups of currently ($n = 7$) and previously ($n = 4$) injured females with minor injuries ($G = 0.045$, df = 1, $p = 0.874$). No difference was detected between the survivorship of pups of females with minor injuries (currently and previously injured classes pooled) and uninjured females ($G = 2.56$, df = 1, $p = 0.126$).

### *Parental investment*

Females with major injuries did not appear to invest significantly less in their pups than did uninjured females. The parental investment period of previously injured females with major injuries ($n = 6$, $\bar{x} = 38.8 \pm 5.6$ d) was similar to that of uninjured females ($n = 74$, $\bar{x} = 41.1 \pm 3.8$ d; Mann–Whitney normal approximation, $t = 0.918$, $p = 0.179$). Currently injured females with major injuries ($n = 2$) invested the same amount of time in their pups ($\bar{x} = 40 \pm 1.0$ d) as previously injured females (Mann–Whitney $U$-test: $U = 6.5$, $p > 0.5$). When both currently and previously injured classes were combined, females with major injuries ($n = 8$) invested a similar amount of time in their pups ($\bar{x} = 39.13 \pm 4.8$ d) to uninjured females (Mann–Whitney normal approximation: $t = 0.981$, $p = 0.163$).

The parental investment period of currently injured females with minor injuries ($n = 6$, $\bar{x} = 41.8 \pm 4.2$ d) did not differ significantly from that of previously injured females ($n = 2$, $\bar{x} = 41.5 \pm 3.5$ d; Mann–Whitney $U$-test: $U = 11$, $p > 0.05$). Injured females (currently and previously injured classes combined, $n = 8$, $\bar{x} = 41.75 \pm 3.8$ d) and uninjured females had similar investment in their pups (Mann–Whitney normal approximation: $t = 0.723$, $p = 0.235$).

### *Frequency of injury and mortality of females*

Thirty-seven of 55 adult female seals (67%) did not sustain a major injury in 1988 or 1989 (Table 3). The distribution of the number of major injuries per year for adult female seals did not differ significantly from a Poisson distribution ($G = 1.87$, df = 1, $p > 0.1$).

Eight of 55 permanently identified adult female monk seals

TABLE 2. Survivorship through the first year of life of pups of injured and uninjured female Hawaiian monk seals, Laysan Island, northwestern Hawaiian Islands, 1983–1989

| | Females with major injuries | | Females with minor injuries | | Uninjured females |
|---|---|---|---|---|---|
| | Current[a] | Previous[b] | Current[a] | Previous[b] | |
| No. of pups that survived | 2 (29) | 9 (69) | 3 (43) | 2 (50) | 79 (65) |
| No. of pups that did not survive | 4 (57) | 4 (31) | 4 (57) | 2 (50) | 33 (27) |
| No. of pups with fate unknown | 1 (14) | 0 (0) | 0 (0) | 0 (0) | 9 (8) |
| Total no. of pups | 7 | 13 | 7 | 4 | 121 |
| Total no. of females | 7 | 25 | 7 | 7 | 201 |
| % of females with pup | 100 | 52 | 100 | 57 | 60 |

NOTE: Numbers in parentheses are percentages.

[a] Seals injured before or during parental investment.

[b] Seals injured in the previous year after the end of parental investment, or during a year in which they were not seen with a pup.

TABLE 3. Number of major injuries per year for adult female Hawaiian monk seals at Laysan Island, northwestern Hawaiian Islands, 1988 and 1989

| No. of injuries per year | Number of female monk seals | | | Expected frequency |
|---|---|---|---|---|
| | 1988 | 1989 | Pooled | |
| 0 | 25 | 12 | 37 | 34.28 |
| 1 | 5 | 7 | 12 | 16.21 |
| 2 | 1 | 3 | 4 | 4.43 |
| 3 | 2 | 0 | 2 | |
| Total | 33 | 22 | 55 | |

NOTE: Expected frequencies are generated from a Poisson distribution.

TABLE 4. Numbers of immature female Hawaiian monk seals injured in the transitional (T; aged 4–8 years) and prereproductive (P; aged 0–3 years) classes at Laysan Island, northwestern Hawaiian Islands, 1988 and 1989

| | 1988 | | 1989 | | Pooled | |
|---|---|---|---|---|---|---|
| | P | T | P | T | P | T |
| No. of females injured | 4 | 4 | 3 | 12* | 7 | 16* |
| Total no. of injuries | 4 | 7* | 3 | 15* | 7 | 22* |
| No. of females not injured | 46 | 23 | 41 | 20 | 87 | 43 |
| Total no. of females | 50 | 27 | 44 | 32 | 94 | 59 |

*Significant difference between transitional and prereproductive classes.

died in 1983–1989. All eight had sustained injuries inflicted by adult male monk seals shortly before their death. Two unidentified adult females died of unknown causes, perhaps age-related, in 1983; however, one had two small punctures on her back and the other carcass was being mounted by an adult male seal. Six unidentified females died in 1983–1989; all had sustained injuries inflicted by adult male monk seals. Of the uninjured females, three (two in 1983, one in 1988) that were easily identified by natural marks were not seen in any subsequent years. Thus, 14 of 16 adult females that died had been injured by adult males shortly before their death.

One untagged immature female and 4 of 26 females aged 3–6 years died after sustaining injuries from adult male seals. Two immature females identified from flipper tags disappeared after sustaining adult male inflicted injuries, and were not seen in subsequent years.

### *Effect of injuries on recruitment of immature females*

In 1988, no significant difference was detected in the proportion of transitional immature female seals aged 4–8 years ($n = 4/27$) and prereproductive females aged 0–3 years ($n = 4/50$; $G = 0.78$, df = 1, $p = 0.442$; Table 4) that were injured by males. Although the difference between the two classes was not statistically significant, wounding of transitional females (15% of the class) was almost double that of prereproductive females (8% of the class), which is consistent with the results from 1989, when a greater proportion of transitional than prereproductive immatures was injured ($n = 12/32$ and $3/44$, respectively; $G = 10.86$, df = 1, $p < 0.001$). Moreover, many females in the transitional class, but none in the prereproductive class, were injured more than once (Table 4). The number of injuries per female was significantly greater for the transitional class than for the prereproductive class in both years (1988: $G = 4.16$, df = 1, $p = 0.043$; 1989: $G = 16.56$, df = 1, $p < 0.001$). The proportion of immature females in the transitional class that were injured by adult males in 1988 and 1989 ($n = 16/59$; Table 4) was similar to that of adult females ($n = 18/55$; Table 3; $G = 0.42$, df = 1, $p = 0.494$).

## Discussion

We cannot conclude that injuries have no effect on reproductive success, though the hypothesis that injuries negatively affect female reproductive success was only weakly supported. Because the sample sizes were small, the power of the tests used to compare injured and uninjured females was low (Table 1), and the probability of committing a type II error was high. The power of a test can be improved by increasing the sample size (Sokal and Rohlf 1981); however, the sample sizes required to find significant differences between injured and uninjured females in our study were in most cases very large (Table 1). The probability of observing injuries with such high frequency in a small population of adult females (55 permanently identified seals) was very low. Despite the low power of the tests, pup survival showed some negative effects due to injury. Pups of females with major injuries appeared to survive less well than those of uninjured females. Pups of injured females (all classes pooled) had significantly lower survivorship to weaning than pups of uninjured females, and pups of currently injured females with major wounds had slightly lower survival through the first year than pups of uninjured females (Table 2). Thus, despite small sample sizes, there is some evidence that injuries affect female reproductive success.

The timing of an injury to a female could influence the amount of energy she has during lactation, which in turn could affect the pup's survival through its first year. Lactation is energetically costly for females (Young 1976). Because female phocids generally do not feed during lactation, they use a significant proportion of their energy reserves to feed their pups. For example, female grey seals use 85% of their stored energy resources while nursing their offspring (Fedak and Anderson 1982), northern elephant seals use 58% (Costa *et al.* 1986), and hooded seals (*Cystophora cristata*) use 33% (Bowen *et al.* 1987). A female in poor condition because of a recent injury may have a lower than normal supply of stored fat available for lactation, resulting in reduced pup survival.

Although the survival of pups of currently injured females was not significantly different than for pups of uninjured females (Table 2), there is some evidence that currently injured females use energy, otherwise allocated for lactation, to recover from injuries. Two female monk seals that sustained severe injuries inflicted by sharks shortly prior to pupping at French Frigate Shoals (latitude 23°45′N, longitude 166°10′W) in the northwestern Hawaiian Islands could not nurse their pups and eventually abandoned them (M. P. Craig, Honolulu Laboratory, personal communication). One female injured by adult male seals at Kure Atoll (latitude 28°25′N, longitude 178°10′W) also abandoned her pup within days of its birth (J. R. Henderson, Honolulu Laboratory, personal communication).

Poor condition of females before parturition may reduce the survival of their offspring. Female northern elephant seals arriving for the breeding season with fresh shark wounds were less successful at pupping and breeding than uninjured females (Ainley *et al.* 1981; Le Boeuf *et al.* 1982). The pups of injured female elephant seals were stillborn or abandoned soon after birth, or wounded mothers allowed other females to nurse their pups. The injuries sustained by elephant seals affected their ability to successfully wean their pups. Ainley *et al.* (1981) found that females that had raised pups successfully to weaning age in the years prior to their injury were less successful in raising their pup during the year in which they were injured. Thus, wounds that result in the condition of females being poorer than normal apparently cause reduced survival of offspring to weaning.

After weaning, a pup fasts for a number of weeks and may therefore need a minimum amount of energy from the nursing period to survive. The postweaning period is critical because the pup is relatively defenseless and inexperienced, and must live on stored energy until it learns to feed on its own (Reiter *et al.* 1978). Hawaiian monk seal pups lose approximately 15–30% of their weaning weight in the postweaning fast (Kenyon and Rice 1959), and most of the energy used during this period appears to be from blubber accumulated during nursing. About 94% of the energy required by grey seal pups during the first month of their postweaning fast comes from blubber stored during the nursing period (Nordoy and Blix 1985; Worthy and Lavigne 1987). Similarly, harp seal pups obtain 80–90% of their energy from blubber acquired in the nursing period (Worthy and Lavigne 1983, 1987). Because of the high energetic cost of the postweaning fast, a pup weaned at a lighter than normal weight would probably be less likely to survive its first year. Consequently, the first-year survival of pups of currently injured females may be detrimentally affected by their mothers' wounds (Table 2).

In contrast to currently injured females, females injured in the year prior to parturition appear to have recovered sufficiently to store normal energy reserves. Reproductive rate, mean parental investment period, and pup survivorship of previously injured females were not significantly different from those of uninjured seals. Most pregnant grey seals do not start increasing in weight until the time of implantation of the blastocyst (approximately 3–4 months after copulation; Boyd 1984). Johnson and Johnson (1978) found that many Hawaiian monk seal females had regained most of the weight lost during lactation after 42–66 days, before undergoing an extended (20–30 d) stay on shore to moult. Monk seals appear to fast or to eat very little during the moult (Kenyon and Rice 1959). If female Hawaiian monk seals do not begin storing energy for lactation until after they moult, a previously injured female would have several months to recover from her wound before starting to deposit fat reserves for lactation, and her pup would be more likely to receive the full nutritional benefit of lactation than the pup of a currently injured mother.

A wounded female monk seal's reproductive success appears to be influenced by the severity of her injuries. Minor injuries had no detectable effect on the reproductive success of female monk seals. Reproductive rate, mean parental investment period, and survivorship of the pups of currently and previously injured females with minor wounds were the same as for uninjured females. Major injuries negatively affected the reproductive success of currently injured females with respect to pup survivorship (Table 2). Le Boeuf *et al.* (1982) monitored 11 female northern elephant seals with "moderate to severe" fresh wounds and suggested that the injured females successful in raising their pups appeared to have the least severe injuries.

Most of the female seals that died at Laysan Island sustained injuries inflicted by adult males before they died. Some of the females that died did not appear to have injuries that were serious enough to be fatal (Hiruki *et al.* 1993). In these cases, it may have been the continued harassment of the males during a mobbing incident, where several males attempt to mate with a female, that resulted in wounding sufficient to cause death. Some female seals are reinjured often enough in the same year by adult males (Table 3) that the cumulative effect may result in the death of the female. Similarly, female northern elephant seals sometimes die after being harassed by groups of subordinate males (Le Boeuf and Mesnick 1990). A female elephant seal departing from the harem may be chased by several subordinate males, all of which attempt to mount her. During this time, she receives over 20 times more blows, mounts, and copulations than normal, and if she dies, males sometimes compete over her carcass (Le Boeuf and Mesnick 1990). Female mink (*Mustela vison*) have also been known to die after being pursued by, and mating with, several males (Hatler 1972). The female sustains neck injuries during mating, but generally these are not severe enough to be fatal (Hatler 1972). Hatler (1972) has suggested that because the males pursue her frequently, she probably cannot hunt and replenish her energy reserves and dies as a result of the continued harassment.

Immature female Hawaiian monk seals were injured more often by adult males as they entered the reproductive population than when they were prereproductive (Table 4). The proportion of immature females aged 4–8 years with injuries was similar to that of adult females. Immature females sometimes die from these injuries: 4 of 26 females aged 3–6 years in 1988 and 1989 sustained fatal injuries. Mortality of young females is a serious concern with respect to population growth, as their potential productivity is never realized, thus reducing future recruitment into the population.

In summary, the major consequence of injuries for female reproductive success is the increase in female mortality, which shortens their reproductive life. The timing and severity of injuries can affect the survivorship of pups of injured females if the females do not have sufficient time to recover before parturition and lactation. However, if the females have sufficient time between sustaining injuries and parturition, there appears to be no major effect on the survival of pups to weaning and through the first year of life.

## Acknowledgements

We extend our thanks to the Honolulu Laboratory biologists and volunteers who helped collect data: D. Alcorn, M. Brainard, R. Brainard, B. Choy, M. Craig, R. Forsyth, T. Gerrodette, J. Henderson, L. Honigman, and R. Westlake. The support of the U.S. Fish and Wildlife Service, the Hawaiian Islands National Wildlife Refuge Staff, the Canadian Wildlife Service, and the captain, officers, and crew of the NOAA ship *Townsend Cromwell* and the fishing vessel *Feresa* was greatly appreciated. J. O. Murie, S. J. Hannon, L. M. Fedigan, S. A. Boutin, T. Gerrodette, J. F. Hare, T. J. Ragen, and two anonymous reviewers commented constructively on earlier drafts of the manuscript. T. J. Ragen provided insight on the power analysis. This study was done in partial fulfilment of the requirements for a Master's degree to L. M. Hiruki at the University of Alberta and was supported by the Natural Sciences and Engineering Research Council of Canada, the University of Alberta, and the World Wildlife Fund (Canada).

# Horizontal and Vertical Movements of the Shortfin Mako Shark, *Isurus oxyrinchus*, in the Southern California Bight

*David B. Holts*[A] *and Dennis W. Bedford*[B]

[A] National Oceanic and Atmospheric Administration, National Marine Fisheries Service,

*Abstract*

Recreational and commercial fishing effort directed at the shortfin mako shark, *Isurus oxyrinchus*, off the coast of southern California increased markedly in the mid 1980s. However, very little is known about the population size, stock structure or movements of these sharks in the northern Pacific. It is important to determine their role in these waters because the southern California bight may be an important pupping and nursery area for shortfin mako sharks.

Acoustic telemetry was used to identify short-term horizontal and vertical movements of three shortfin mako sharks in the southern California bight during the summer of 1989. All three sharks were two-year-old juveniles and were tracked for periods of from 18 to 25 h. They spent 90% of their time in the mixed layer, with only infrequent excursions below the thermocline. Vertical and horizontal movements did not indicate any diel activity pattern associated with distance to the shore or nearby islands or with bottom topography.

*Extra keywords:* tagging, tracking, water temperature.

## Introduction

Recreational and commercial fishing effort directed at the shortfin mako shark, *Isurus oxyrinchus*, off the coast of southern California increased markedly during the 1980s (Holts 1988). Popular interest in the shortfin mako shark as a sportfish and consumer acceptance of it as a commercial foodfish encouraged continued harvests. Popularity with sportfishers on both chartered sportfishing vessels and private boats has increased by an order of magnitude in recent years. Estimated fishing effort in angler trips (number of individual angler fishing trips) increased from 41 000 in 1986 to more than 410 000 in 1989 and may still be increasing (S. Crook, California Dept. of Fish and Game, personal communication). Approximately 90 to 180 t (metric tonnes dressed weight) of shortfin mako sharks are taken commercially as an incidental catch in the Californian drift-net fisheries for thresher sharks, *Alopias vulpinus*, and swordfish, *Xiphias gladius* (Bedford and Hagerman 1983; Holts 1988; Hanan *et al.* 1993). An experimental longline fishery targeting shortfin mako sharks began off southern California in 1988 and continued through the 1991 fishing season. An additional 68 t of shortfin mako sharks were landed annually in this fishery. Total commercial landings of shortfin mako sharks for all southern Californian coastal fisheries exceeds 200 t annually. This has raised concerns about the ability of the resource to sustain the current level of fishing pressure. Very little is known about the population size, stock structure, distribution or movements of the shortfin mako shark off the US Pacific coastal states. Catch records from the California Department of Fish and Game indicate that the fisheries take shortfin mako sharks primarily within 93 km of shore and from the California–Mexico border to as far north as San Francisco. They are available in greatest abundance in the spring and summer months; catches are greatest between June and August.

0067-1940/93/060901$05.00

The catch is composed almost entirely of juvenile 1- and 2-year-old fish weighing from 13·6 to 27·2 kg (Hanan *et al.* 1993). The southern California bight may serve as a nursery area for newborn and juvenile shortfin mako sharks (Holts and Bedford 1989).

Shortfin mako sharks grow slowly, mature relatively late in life, and have a long gestation period (Pratt and Casey 1983). They produce a few (generally 4 to 16) well developed pups (Stevens 1983) whose survival is assumed to be good because of their advanced development at birth. This life-history strategy makes these sharks quite vulnerable to modern commercial and recreational fishing operations.

Information on distribution and short- and long-term movement patterns is necessary in assessing the status of affected stocks and in determining management options should management of coastal shark fisheries become prudent. Conventional dart-tagging studies in the north-western Atlantic have yielded considerable information concerning long-term movements of shortfin mako sharks in that area (Casey and Kohler 1992), but studies conducted off the southern Californian coast have only begun to reveal long-term movements of shortfin mako sharks there. Still less is known about the short-term behaviour of individuals. Acoustic telemetry has proved to be useful in identifying the short-term horizontal and vertical movements of several shark species (Carey 1990; Carey and Scharold 1990; Nelson 1990) and other large pelagic fish species (Carey and Robison 1981; Holland *et al.* 1990*a*, 1990*b*; Holts and Bedford 1990; Brill *et al.* 1993).

During the summer of 1989, four five-day cruises were conducted through a cooperative agreement between the Southwest Fisheries Science Center and the California Department of Fish and Game. The primary objective was to determine short-term movements and activity patterns of shortfin mako sharks in the waters off southern California by using acoustic telemetry.

## Materials and Methods

The 18-m sportfishing vessel *Pacific Clipper* was chartered from 14 August to 15 September 1989. The acoustic tracking techniques and equipment used in this study were identical to those previously described for tracking striped marlin (Holts and Bedford 1990). This involved the use of a hull-mounted directional hydrophone and ultrasonic receiver (Vemco[1] CS40 and VR60, respectively) to indicate direction and approximate distance to the tagged shark. The acoustic transmitter tags (Vemco[1] V4P) had working pressures of 100 psi and 500 psi (working depths of 0 to 70 m and 0 to 340 m, respectively). The tracking vessel remained within 400 m of the fish, and loran-C coordinates were recorded every 15 min for horizontal positioning. Temperature profiles of the water column were measured with expendable bathythermographs approximately every 6 h.

Sharks were captured by rod and reel. Terminal tackle consisted of a 5-m length of leader constructed from braided wire (250-pound test) and a size '9/0' hook baited with Pacific mackerel, *Scomber japonicus*, or Pacific sardine, *Sardinops sagax*. Sharks were attracted to the vessel by chumming with finely chopped mackerel. Of 28 shortfin mako sharks captured, only the three largest were selected for tagging with acoustic transmitters. To minimize capture trauma, these sharks were quickly brought alongside the boat, where the transmitters were attached with a hand-held harpoon applicator without removing the sharks from the water. They were then released by cutting the leader as close to the hook as possible. Tracking commenced immediately after each fish was released. Total length and weight were estimated while the fish was being tagged.

## Results

All three sharks were tagged and tracked off Oceanside, California, in the channel formed by Santa Catalina and San Clemente Islands (Fig. 1). Tracking periods ranged from

**Fig. 1.** Horizontal movements of three shortfin mako sharks acoustically tracked in the southern California bight, August–September 1989. SR, sunrise; SS, sunset.

18 to 25 h and covered 24 to 57 km. Data for both horizontal movements and vertical depth variations were obtained for all tracks. The location of the shark was assumed to be the same as that of the tracking vessel. Loran-C positions recorded every 15 min were smoothed with a running average over 90-min periods to indicate rate of movement.

The first shortfin mako shark tracked (Shark M89-1) was estimated to be a 1·8-m, 36-kg female and was tagged at 1300 hours on 15 August 1989. It was released 18 km north of the '181 Fathom Bank' (at 33°06′N,117°52′W), and it moved 30 km in a generally southerly direction over the next 25 h (Fig. 1). The overall rate of movement was 1·10 km $h^{-1}$ (Fig. 2). Speed decreased from about 2·0 km $h^{-1}$ after release to less than 0·74 km $h^{-1}$ just before sunset, then increased markedly to 2·78 km $h^{-1}$ at 2030 hours. Speed gradually declined during the remainder of the night to 0·74 km $h^{-1}$ just after sunrise. Between sunrise and the end of the track, this fish again increased its speed to about 1·80 km $h^{-1}$.

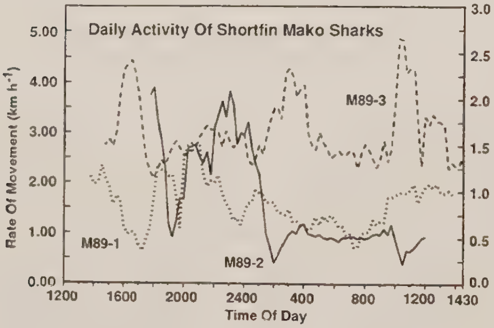

**Fig. 2.** Daily activity, in kilometres per hour and nautical miles per hour, for three shortfin mako sharks tracked in the southern California bight, August–September 1989.

This shark initially sounded to 35 m but slowly ascended over the next 45 min to about 7 m, where it remained until 1630 hours (Fig. 3). Between 1630 and 2000 hours, it made

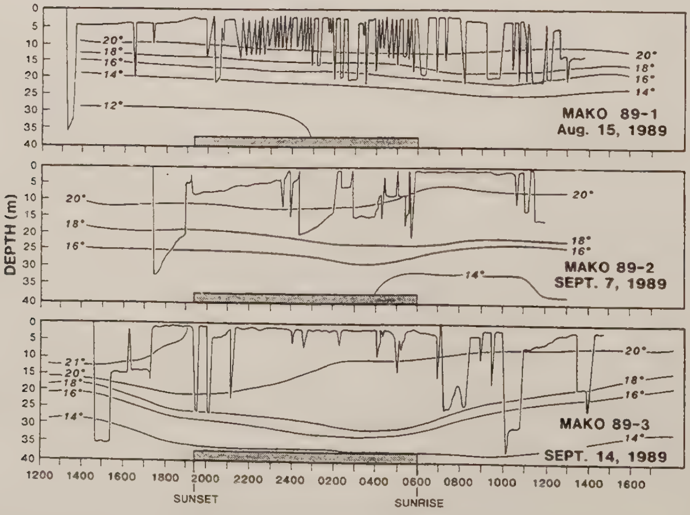

**Fig. 3.** Diving profiles for three shortfin mako sharks in the southern California bight, August–September 1989. Temperatures shown in °C.

two short-duration dives, returning each time to a depth of 4 to 5 m. Sunset occurred at 1930 hours, and the shark began making numerous, almost rhythmic, dives between 3 and 20 m. This pattern continued until sunrise and totalled 32 dives, or an average of 3·5 dives $h^{-1}$. The deepest and longest of these was to 21 m for 23 min at 0300 hours. Dive frequency decreased to less than 2 dives $h^{-1}$ soon after sunrise. This shark spent little time below the steepest gradient of the thermocline.

The second shark tracked (Shark M89-2) was a 1·7-m individual estimated to weigh 32 kg. Its sex was not determined. Tagging and release occurred 30 km north of the '181 Fathom Bank' (i.e. at 32°54′N,117°53′W) at 1730 hours on 7 September 1989 (Fig. 1). This shark travelled 24 km north-west in 18 h and averaged 1·29 km $h^{-1}$ during the daylight hours and 1·48 km $h^{-1}$ at night. As with Shark M89-1, speed decreased from a post-release high of 3·7 km $h^{-1}$ to less than 0·92 km $h^{-1}$ just after sunset. Speed then increased through midnight but decreased to about 0·92 kn $h^{-1}$ for the remainder of the track (Fig. 2). Prior scheduling required the tracking of Shark M89-2 to be terminated after only 18 h.

After release, this second shark immediately descended to 33 m, where it remained for 90 min before gradually ascending to 20 m (Fig. 2). At 1900 hours, just before sunset, it ascended quickly to about 5 m, where it remained until 2000 hours. It remained above 10 m until about midnight, when it descended to 29 m and slowly rose to 12 m over the next couple of hours. A series of short dives followed until sunrise, when the frequency and depth of dives decreased. Shortly after sunrise, it positioned itself between 2 and 4 m, where it remained for the next 4 h. Another series of short dives commenced at 1030 hours. These dives may have been influenced by our attempts to position the tracking boat in the path of the fish in an unsuccessful effort to recapture this individual. The top of the thermocline varied between 18 and 22 m in depth during this track, but the shark did not descend into it except for the initial plunge.

The third shark tracked (Shark M89-3), a 1·8-m, 32-kg individual, was tagged at 1430 hours on 14 September 1989. Sex was not determined. This fish was tagged 31 km east of the '181 Fathom Bank' (i.e. at 32°47′N,117°34′W), and it moved west-north-west, passing over a shoal area near the '181 Fathom Bank' and covering 57 km during the 24-h tracking period (Fig. 1). This shark differed from the other two by covering nearly twice the distance and averaging 2·40 km $h^{-1}$ (Fig. 2). The speed of this shark increased to more than 4·44 km $h^{-1}$ during the first 3 h of the track, and then decreased to almost 2·0 km $h^{-1}$. Speed then remained at about 2·40 to 2·77 km $h^{-1}$ for most of the remainder of the track, with noticeable increases at 0200 and 1000 hours.

When released, Shark M89-3 also sounded to 33 m. Within 1 h it ascended to 15 m, where it remained until 1715 hours (Fig. 3). It then rose to within 1 m of the surface. Just after sunset, it made three dives to 20–25 m. It remained within 3 m of the surface during the night. After sunrise, it descended to 22 m for about 1 h before rising to near the surface. Its deepest dive to 33 m occurred at 1000 hours. This dive and a final one to 19 m at 1300 hours each lasted about 1 h and were well into the upper portion of the thermocline.

## Discussion

### *Post-tagging Dive and Survival*

All three shortfin mako sharks were released in good condition and showed no apparent harmful effects from being tagged throughout the tracking period. There was no apparent trauma from capture extending beyond the post-tagging dive.

Vertical dive profiles indicate that the trauma of capture and release may last only 30 to 90 min. Horizontal movements of Sharks M89-1 and M89-2 support this observation. The actual speed of these two sharks decreased substantially within 2 h of release. The third shark (M89-3) increased its speed over the first 2 h while it remained at a depth of 30 m, then slowed as it ascended into the mixed layer.

An initial dive into the cooler waters below the thermocline immediately following release has been noted for blue sharks, *Prionace glauca*, by Sciarrotta and Nelson (1977), Tricas (1979) and Nelson (1990) and for billfish by Holland *et al.* (1990*a*) and Holts and Bedford (1990). This may be a response of obligate ram ventilators to overcome an oxygen debt built up during capture, as suggested by Holland *et al.* (1990*a*). This is certainly possible in the present case because shortfin mako sharks are active fish when caught on sportfishing gear and undoubtedly expend considerable energy attempting to escape. Both muscular and visceral temperatures in the shortfin mako shark are maintained well above ambient water temperature through a system of vascular counter-current heat exchangers (Carey *et al.* 1981, 1985). The time spent in these post-tagging dives may also be a behavioural response to regulate internal temperature by dissipating excess heat built up during the catching and tagging process.

### *Horizontal Movements in the Southern California Bight*

The southern California bight has a diverse topography that includes several large islands ranging in distance from 20 to 110 km from the Californian shore. The average water depth is 700 to 1000 m in the immediate tracking area, although numerous submarine escarpments and banks rise to within 100 m of the surface. The southern California bight is also influenced by the California Current and counter-current, which forms many eddies in and around the islands. These currents and resulting eddies probably influenced the movement of the sharks we tracked. Water currents were found to influence the movement of striped marlin off the island of Hawaii (Brill *et al.* 1993). Unfortunately, the measurement of water currents and eddies requires current-profiling systems not available on small tracking vessels.

All three tracks in this study began and ended within a few kilometres of various submarine features within the southern California bight. However, there was no clear indication that any of the sharks tracked were actually associated with these features. Each capture and tagging location was influenced by drift because our 'chumming line' extended over several kilometres at times.

Shark M89-1, although moving generally south, varied its direction considerably more than did Sharks M89-2 and M89-3. These last two sharks both travelled in a fairly direct westerly direction. Sharks M89-1 and M89-2 averaged $1\cdot33$ km $h^{-1}$ over the tracking period (Fig. 3). Shark M89-3 travelled nearly twice as far as the others, averaging $2\cdot55$ km $h^{-1}$. The rate of movement in the first hour of tracking exceeded $1\cdot80$ km $h^{-1}$ for all three fish. M89-1 and M89-2 both slowed considerably in the first few hours after release, whereas M89-3 first increased its speed to nearly $4\cdot44$ km $h^{-1}$ before slowing to $2\cdot77$ km $h^{-1}$. The average rate of movement for all three fish was lowest during the early to mid-morning hours. One shortfin mako shark (about the same size as our fish) tracked off the eastern coast of the USA averaged about $3\cdot70$ km $h^{-1}$ without any apparent change in swimming pattern, although it did reach $5\cdot55$ km $h^{-1}$ for a short time (F. Carey, personal communication). White sharks, *Carcharodon carcharias*, tracked off southern Australia averaged $3\cdot2$ km $h^{-1}$ (Strong *et al.* 1992).

Satellite images of sea surface temperatures (SSTs) were obtained for each track. Several temperature breaks and current eddies of 1°C to 2°C were present in and around the islands of the southern California bight. The SST image associated with the track of Shark M89-1 was obscured by clouds. The track of Shark M89-2 stayed on the warm side of a 2°C temperature break as the fish moved west toward the Avalon Bank. The track of Shark M89-3 crossed two temperature gradients as the fish moved from warmer water off La Jolla, California, to water 2°C to 3°C cooler as it moved west. Neither of these two sharks showed any sign of changing their behaviour in response to SSTs as did the striped marlin tracked earlier in the same area (Holts and Bedford 1990).

### *Vertical Distribution and Temperature Preferences*

A major feature of this study is that the three juvenile shortfin mako sharks observed in the southern California bight oriented to the surface waters above the thermocline. They spent 90% of the total tracking time in the mixed layer above 20 m. Slightly more daylight hours than night-time hours were spent below 20 m (Fig. 3).

The track of Shark M89-1 showed considerably more vertical activity than did the tracks of the other two sharks. M89-1 spent most of the night-time hours in continual vertical excursions between 2 and 15 m. The frequency of excursions slowed considerably after sunrise, although activity remained high through the end of the tracking period. Tracks from M89-2 and M89-3 showed fewer vertical excursions, but several of these lasted 1 h or longer. Vertical excursions of M89-1 and M89-2 were greatest during the night, whereas M89-3 was most active during the mid-morning period of the second day. These sharks did not descend below 25 m during the night-time hours, and, excluding the post-tagging plunge, only one (M89-3) descended below 25 m during the day.

Depth of the thermocline averaged 14–16 m during the first track and 19 to 20 m during the second and third. In all tracks, the mixed layer was 20°C to 21°C and the steepest gradient in the thermocline occurred from 18°C to 20°C. The total time that all three sharks spent in the mixed layer was 81·6%, with another 11·4% spent in the 18°C to 20°C transition zone (Table 1). Only infrequent or short excursions below the thermocline occurred, and there was little difference between day and night. Only vaguely apparent in this study were patterns observed for blue and shortfin mako sharks in the Atlantic. Those sharks made their longest excursions and deeper dives during the day and smaller vertical excursions at night. In that study, a large female shortfin mako shark spent most of the time well below the mixed layer and reached depths greater than 400 m several times (Carey and Scharold 1990). Our sharks were smaller than the shortfin mako and blue sharks tracked by Carey and Scharold (1990). The reason for observed differences in depth preference is unknown, although condition, age and location may all be involved.

Several other pelagic predators prefer the warmer water of the mixed layer, including the blue shark (Sciarrotta and Nelson 1977) and the striped marlin (Holts and Bedford 1990). Still others, including the white shark (Carey *et al.* 1982) and the yellowfin tuna, *Thunnus albacares* (Carey and Olson 1982; Yonemori 1982), orient to the steepest gradient of the thermocline.

**Table 1. Percentages of time spent at different temperatures during day (D) and night (N) for shortfin mako sharks**

| Temperature (°C) | Shark M89-1 | | Shark M89-2 | | Shark M89-3 | | Combined | | Total |
|---|---|---|---|---|---|---|---|---|---|

### *Diel Patterns*

Neither horizontal nor vertical movements indicated any diel activity pattern common to all three sharks. Likewise, no pattern of movement such as a home range associated with the nearby islands, the banks or the shore was evident, probably owing to the diverse topography in the area. Sciarrotta and Nelson (1977) observed an island-oriented onshore–offshore movement in blue sharks associated with feeding. Interisland cruising and island patrolling were described for white sharks (Strong *et al.* 1992). The shortfin mako sharks tracked in the present study were not obviously orienting to any features. At this age, in the southern California bight, juvenile shortfin mako sharks may have an extensive home range as do shortfin mako sharks in the Atlantic (Casey and Kohler 1992). If this is the case, extended tracks of several days may be necessary to identify any diel activity patterns or island-oriented movements.

### Acknowledgments

This work was supported by the California Department of Fish and Game and the Southwest Fisheries Science Center (SWFSC). We also acknowledge the assistance of Jerry Thompson and Paul Orstrom aboard the *Pacific Clipper*. We are grateful to all the biologists who volunteered their time to assist in this project. Drs David Au and Norm Bartoo of SWFSC and Dr Frank Carey of the Woods Hole Oceanographic Institution provided valuable reviews of the manuscript. Ken Raymond and Roy Allen of SWFSC prepared the figures.

**Abstract.**–Recruitment of individuals from the epipelagic phase to the demersal armorhead *Pseudopentaceros wheeleri* population at Southeast (SE) Hancock Seamount has typically been recognized by the influx of fish with a high fatness index (FI; body depth relative to fork length). Reliance on this index was dictated by the peculiarity of the seamount life history stage in which armorhead cease somatic growth soon after recruitment to the seamount and FI declines during seamount residence until death. Limited sampling opportunities and variability in FI at the time of recruitment preclude the exclusive use of FI as a means of identifying newly arrived recruits among recruits-of-the-year and hence the timing of annual recruitment. Settlement and recruitment to the seamount population are synonymous. Efforts to develop a method of identifying new recruits were initiated by an examination of epipelagic and seamount (SE Hancock) armorhead for differences in macroparasites as well as hepatosomatic and visceral fat-somatic indices. Of the two condition indices, the hepatosomatic index held the most potential but was considered too labile because prerecruits probably experience decreases that vary according to energetic demands during seamount migration. The monogenean gill parasite *Microcotyle macropharynx* was highly prevalent among seamount individuals in all sampling periods but absent from epipelagics. Based on probable rapid infection and maturation, identification of new recruits was based on the absence of mature *M. macrophaynx*. Results indicate that significant new recruitment occurred only during the late spring to midsummer sampling periods, and the mean FI of new seamount recruits was lower than that of comparable size epipelagics.

The armorhead *Pseudopentaceros wheeleri* (Hardy) in the North Pacific Ocean initially occupies an epipelagic and then demersal habitat during its life history. Progeny originate from winter spawning of the demersal armorhead population associated with the summit and upper slopes of the southern Emperor-northern Hawaiian Ridge (SE-NHR) seamounts (Fig. 1) (Bilim et al., 1978; Borets, 1979). Larvae are initially found in surface waters around the seamounts (Fedosova and Komrakov, 1975; Borets, 1979) but soon move or are advected into subarctic waters of the central and northeastern Pacific (Boehlert and Sasaki, 1988). Here they feed in oceanic surface waters and undergo somatic growth, accumulate energy reserves, but experience no reproductive development. These epipelagic individuals appear deep-bodied and display a striking pattern of blue and silver blotches along their dorsal and lateral regions. The process and timing by which epipelagic individuals recruit back to the SE-NHR seamounts is not well understood (Boehlert and Sasaki, 1988). Individuals are primarily 28–33 cm fork length (FL) upon recruitment to the SE-NHR seamounts (Humphreys et al., 1989). Since recruits are similar in length and co-occur among the resident seamount population, settlement and recruitment to the seamounts are considered synonymous events (Humphreys et al., 1989). Unlike the epipelagics, the seamount population is demersal and virtually uniform in length, but morphologically variable. Three morphological variants (the "fat," "intermediate," and "lean" morphotypes) were previously recognized and found to represent different stages of the demersal seamount phase (Humphreys et al., 1989). This variation intergrades from the deep-bodied, overall bluish-gray coloration of presumably recent recruits (fat morphotype) through progressively leaner forms of uniformly brownish coloration (intermediate and lean morphotypes). Relative body depth refers to the ratio of body depth at first anal spine to FL and hereafter is called the fatness index (FI; Somerton and Kikkawa, 1992). Usage of FI values recognizes that these variations form a continuum rather than discrete changes and has replaced classification by morphotype (Somerton and Kikkawa, 1992). Declining FI reflects the transformation by individuals as the elapsed time of seamount residence increases. During this phase, somatic growth ceases upon recruitment, and stored energy reserves are eventually mobilized for reproductive development and spawning. These processes contribute to the decline in FI and ultimately lead to death (Humphreys et al., 1989).

The discovery of large aggregations of armorhead over the summits and upper slopes of SE-NHR seamounts (Fig. 1) during exploratory work by the former Soviet Union in 1967–1969 (Komrakov, 1970) led to a full-scale bottom trawl fishery in this region by both Japanese and the former Soviet trawl fleet (Uchida and Tagami, 1984). By the end of 1975, the cumulative combined fleet catch of armorhead was some 880,000 metric tons (t). Total annual catch of armorhead by the Japanese trawl fleet declined dramatically after 1976 (Humphreys et al., 1984) and continues to remain low throughout the SE-NHR region (R. Humphreys, unpubl. data). In 1977 the Hancock Seamounts, located in the southermost portion of the SE-NHR trawl fishery, came under U.S. jurisdiction with the implementation of the 200-mile fishery conservation zone (Humphreys et al., 1984). During 1978–1984, several Japanese trawlers were allowed to fish the Hancock Seamounts but were regulated by permit and an annual catch quota (Uchida and Tagami, 1984;

Figure 1

The major habitat of dermersal armorhead is located over the southern Emperor-northern Hawaiian Ridge (SE-NHR) seamounts extending from Koko Seamount to the northwest down through the Hancock Seamounts in the southeast region.

Somerton and Kikkawa, 1992). Owing to sustained low annual catches at the Hancock Seamounts, the National Marine Fisheries Service (NMFS) Honolulu Laboratory implemented both a research stock assessment program in 1985 and recommended institution of a moratorium (in effect since 1986) prohibiting trawl fishing at the Hancock Seamounts (Somerton and Kikkawa, 1992). The remainder of the SE-NHR seamounts, which represent some 90% of the historical trawl fishery in terms of habitat and overall catch, lie in international waters and under no fishery management control. As increases in armorhead biomass at Hancock and other SE-NHR seamounts appear to depend exclusively on recruitment, recent work has focused on examining the temporal pattern of seamount recruitment and the biological characteristics of new recruits. Boehlert and Sasaki (1988) used monthly length-weight data recorded by the Japanese at four SE-NHR seamounts during May 1972–December 1973 to estimate the seasonality of recruitment. Assuming that new recruits have a condition factor of ≥2.0, they found recruitment highest during April–May 1973 and secondary peaks in August 1972 and July 1973. Annual recruitment to Southeast (SE) Hancock Seamount, one of two guyots composing the Hancock Seamounts, was sporadic between 1978 to 1990. Strong recruitment (≥50% of population biomass) at SE Hancock Seamount occurred only in 1980 and 1986, and moderate recruitment (ca. 20–30% of population biomass) in 1988 and 1990, based on catch per unit of effort (CPUE) and FI distributions derived from Japanese trawl data and NMFS stock assessment surveys (Somerton and Kikkawa, 1992).

Little further progress, however, has been made in discerning the timing of recruitment and biological characteristics of newly arrived recruits. The apparent temporal variability in recruitment, the change in FI during time elapsed between recruitment and sampling, coupled with limited sampling opportunities, make the identification and study of new recruits and their temporal recruitment pattern problematic. A potential alternative for identifying newly recruited armorhead uses biological indicators to distinguish a new seamount arrival from longer resident armorhead. Parasites have been frequently used as biological indicators in fish and their benefit to studies of fish stock separation, movement, and diet are numerous (Williams et al., 1992). In relation to seamount studies, differences in the trematode parasite fauna of sablefish off Canada's west coast led Kabata et al. (1988) to surmise that seamount populations of sablefish are distinct and separate from those sablefish inhabiting the continental slope. Since seamount armorhead populations are derived from epipelagic individuals, we examined specimens of both life history phases for parasite differences and other distinguishing features. We report on the feasibility of using a monogenean gill parasite and two condition indices as potential indicators of new seamount recruits.

## Methods

Epipelagic specimens of *P. wheeleri* ($n = 53$) were incidentally captured from the central North Pacific (around lat. 45°N, long. 155°W) in July 1984 and 1985 and from the eastern North Pacific (around lat. 46°N, long. 129°W) in July 1985 by the Japanese fishing vessels *Oshoro Maru* and *Tomi Maru No. 88*, respectively, during salmon longline and surface drift gillnet operations. These specimens were saved intact and stored frozen prior to examination. Specimens of seamount armorhead ($n = 1{,}220$) were collected from the southern end of the SE-NHR at SE Hancock Seamount (29°48'N, 179°04'E; see Fig. 1) by bottom longline gear during research cruises of the NOAA ship *Townsend Cromwell* in June 1985, August and October 1986, April and August 1987, and January, July, August, and November 1988. All seamount specimens were derived from efforts beginning in 1985 to estimate armorhead relative abundance (catch per unit of effort) at SE Hancock Seamount by using standardized assessment techniques described in Somerton and Kikkawa (1992). Seamount specimens were either saved intact and stored frozen, or gills and viscera were removed and preserved at sea in either alcohol-formalin-acetic acid (AFA) solution or placed in a dilute (0.0004%) formalin solution for several hours and then preserved in 10% formalin. Collection data for armorhead specimens included body weight, FL, body depth at first anal spine, sex, and date and location of capture. Measurements were made to the nearest millimeter, and body weight to nearest gram.

Under a dissecting microscope, the gill arches and visceral organs of armorhead specimens were examined for macroparasites. Guidelines proposed by Sindermann (1983) were followed to determine which species have potential as biological tags. Ideal parasite characteristics include ease of detection and identification, a single host-life cycle, and temporal stability in prevalence. Furthermore, the parasite should persist in the host during the study, and prevalence should differ significantly between study areas. These criteria were best fulfilled by the monogenean *Microcotyle macropharynx* (Mamaev), based on examinations of the seven parasite taxa (monogenean *Trochopus* sp., digenean *Bivesicula* sp., larvae of the nematode *Anisakis* type I, nematode *Hysterothylacium* sp., an unidentified caligoid copepod, and juveniles of an unidentified gnathiid isopod) found in the epipelagic and seamount armorhead collected in June 1985 and August 1986. Subsequent examinations of armorhead were restricted to the gills where *M. macropharynx* were exclusively found. Specimens of *M. macropharynx* were readily distinguished from *Trochopus* sp. by the disk-shaped opisthaptor of the latter monogenean. All specimens of *M. macropharynx* were initially identified as that of *M. sebastis* though the pharynx of these specimens appeared to be unusually large[1]. During the review process, a new species description (Mamaev, 1989) of the monogenean *M. macropharynx* collected in 1969–70 from *P. richardsoni* (=*P. wheeleri*) in the Hawaiian Islands region was brought to the attention of the senior author. Subsequently specimens initially identified as *M. sebastis* were re-examined and all found to be *M. macropharynx*[2]. The large pharynx (in relation to the anterior suckers) of *M. macropharynx* distinguishes this species from all other species of *Micocotyle* (Mamaev, 1989). Each *M. macropharynx* was staged as either immature or potentially mature, based on absence or development of the paired yolk ducts, respectively. These organs are the last to develop before egg development in the related species *M. sebastis* (Thoney, 1986). All parasite taxa were saved and stored in 70% ethyl alcohol. Prevalence and mean intensity of *M. macropharynx* in seamount armorhead were computed for each sampling period. Following the terminology defined in Margolis et al. (1982), prevalence (expressed as a percentage) refers to the number of host species infected with a particular parasite species, divided by the number of hosts examined; and mean intensity is derived by dividing the total number of a particular parasite species by the number of individual hosts infected by that parasite. Prevalence and mean intensity data from seamount armorhead were partitioned into two FI groups of <0.26 and ≥0.26. This grouping is based on the observation that 0.26 was the lowest FI found for epipelagic armorhead in this study and thus a possible minimum FI for newly arrived seamount recruits.

Liver and visceral fat weights were also determined for the 27 epipelagic armorhead >27.5 cm FL (of comparable length to seamount individuals) and 410 seamount armorhead collected during October 1986 ($n$ = 115) and January ($n$ = 195), July ($n$ = 18), and November 1988 ($n$ = 82). Liver and visceral fat deposits were removed from the body cavity, blotted dry, and weighed to the nearest 0.1 g. Liver and visceral fat weights are expressed in relation to total body weight and referred to as the hepatosomatic index (HSI) and visceral fatsomatic index (VFSI), respectively. Data was arcsine transformed and tested for normality with the Lilliefor's method of the Kolmogorov-Smirnov test (Wilkinson, 1990). Sample means were compared by either $t$-test, or by Mann-Whitney test if samples remained nonnormal (Wilkinson, 1990).

Estimates of the proportion of recruits-of-the-year to the total SE Hancock armorhead population during each sampling period were based on stock-assesssment-derived FI distributions of the armorhead population. That proportion of the FI distribution ≥0.26 were considered recruits-of-the-year. Data and procedures used to calculate the population FI distribution are presented in Somerton and Kikkawa (1992). The proportion of recruit-of-the-year armorhead in each sampling period un-infected by mature stages of *M. macropharynx* was estimated from results of the prevalence data for those armorhead (from samples examined for *M. macropharynx*) with a FI ≥0.26.

## Results

*Microcotyle macropharynx* were not present in any of the 53 epipelagic armorhead examined but were present in all 775 seamount armorhead with FI <0.26 and in 417 (93.7%) of 445 specimens with FI ≥0.26. Among seamount armorhead with FI <0.26, both the combined (irrespective of maturity stage) category and the immature and mature stage of *M. macropharynx* were highly prevalent (>75%) in all nine sample periods surveyed (Table 1). A similar pattern of high *M. macropharynx* prevalence was found among the seamount armorhead with FI ≥0.26 although instances of lower prevalence appear during the two earliest sample periods (Table 1). Mean intensity of immature *M. macropharynx* in both FI groups was considerably lower in each sample period than the corresponding mean intensities of the mature stage and combined category (Table 2). Mean intensity of mature stage *M. macropharynx* in each sample period and FI group was sufficiently high to ensure easy detection in armorhead infected with mature stage individuals of this monogenean. A wide range in sizes of *M. macropharynx*, including mature stages with eggs, was present among the gills of armorhead, indicating that this parasite has a monoxenous life cycle.

Seamount armorhead without mature *M. macropharynx* represented 5.2% (64) of the 1,220 fish examined. Among those seamount armorhead found un-

infected by mature stage *M. macropharynx*, virtually all were of a FI ≥0.26 (Table 3). The four armorhead with FI <0.26 and uninfected by mature *M. macropharynx* had FI values disjunct from similarly un-infected armorhead with FI ≥0.26 (Fig. 2). Mean FI's of the seamount armorhead group (FI ≥0.26) without mature *M. macropharynx* ($x$ = 0.291) and the epipelagic group ($x$ = 0.307) were significantly different (*t*-test, $P < 0.001$). From samples of seamount armorhead (FI ≥0.26) examined for prevalence of mature stage *M. macropharynx*, the percentage of those found without mature *M. macropharynx* was higher in the June–August samples (Table 3). However, these latter results did not always correspond with peaks in the proportion of the seamount armorhead population (with FI ≥0.26) obtained from stock assess-

**Table 3**

Percent absence of mature stages of the monogenean *Microcotyle macropharynx* from the gills of armorhead *Pseudopentaceros wheeleri* by fatness index (FI) groups of <0.26 and ≥0.26, sampled from Southeast Hancock Seamount during 1985–88. Sample size examined for each category denoted by (*n*).

ment surveys (Fig. 3; data taken Somerton and Kikkawa (1992) from FI distributions for each sample period except November 1988).

Mean HSI ($x = 3.147$; Fig. 4) of the epipelagic group was significantly different from that of seamount armorhead with FI ≥0.26 ($x = 1.358$, Mann-Whitney test, $P < 0.001$) and those with FI <0.26 ($x = 1.028$, *t*-test, $P < 0.001$). Furthermore, none of the seamount armorhead except for two individuals in the FI ≥0.26 group had HSI values exceeding the lowest value (2.154) of the epipelagic group. Differences between the mean HSI of the two seamount FI groups were also highly significant (Mann-Whitney test, $P < 0.001$). Regardless of FI value, the difference in mean HSI between epipelagics and seamount armorhead without ($x = 1.744$, *t*-test, $P < 0.001$) and with ($x = 1.148$, *t*-test, $P < 0.001$) mature *M. macropharynx* remained significantly different, as were differences between the latter two groups (*t*-test, $P < 0.001$). The seamount armorhead group without mature *M. macropharynx* exhibited the least overlap in HSI values with other seamount groups (Fig. 4).

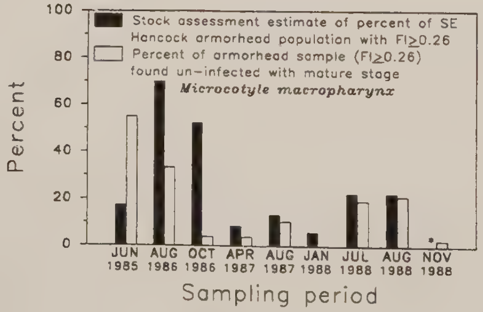

**Figure 3**

Percent of armorhead *Pseudopentaceros wheeleri* samples (fatness index (FI) ≥0.26) without mature *Microcotyle macropharynx* (from Table 3), and the percent of SE Hancock armorhead population with FI ≥0.26; the latter estimated from stock assessment surveys during each of the periods (except November 1988) where armorhead were sampled for *M. macropharynx* infection.

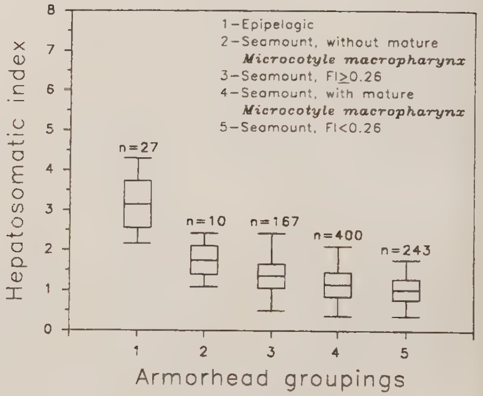

**Figure 4**

Hepatosomatic index by each grouping of armorhead *Pseudopentaceros wheeleri*. The mean is indicated by the midpoint horizontal line within each box, one standard deviation about each mean is denoted by the box, and the range is displayed as the horizontal lines above and below the box.

For the epipelagic group, mean VFSI ($x = 2.152$; Fig. 5) was significantly different from seamount armorhead with FI ≥0.26 ($x = 3.580$, *t*-test, $P < 0.001$) and those with FI <0.26 ($x = 2.933$, Mann-Whitney test, $P = 0.007$). Mean VFSI differences between the latter two seamount groups were also significant (Mann-Whitney test, $P < 0.001$). The mean VFSI of the epipelagic group was also significantly different from that of seamount armorhead with ($x = 3.185$, Mann-Whitney test, $P < 0.001$) and without ($x = 3.663$, *t*-test, $P = 0.009$) mature *M. macropharynx*, whereas the latter two seamount groups did not significantly differ in mean VFSI (Mann-Whitney, $P = 0.364$). Overlap in VFSI among the various groups (Fig. 5) was substantially greater than exhibited for HSI.

## Discussion

The complete absence of the monogenean *M. macropharynx* from all epipelagic armorhead exam-

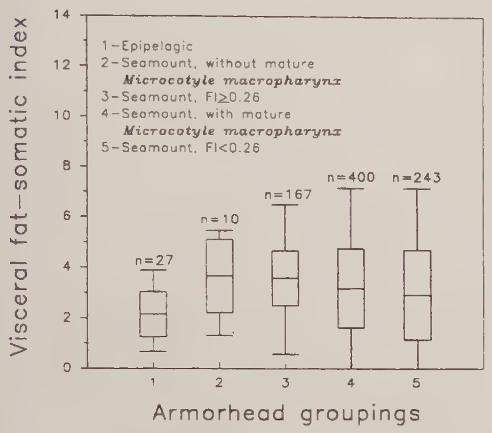

**Figure 5**

Visceral fat-somatic index by each grouping of armorhead *Pseudopentaceros wheeleri*. The mean is indicated by the midpoint horizontal line within each box, one standard deviation about each mean is denoted by the box, and the range is displayed as the horizontal lines above and below the box.

ined, and its high prevalence among seamount armorhead during all sample periods, support the notion that infestation of this parasite originates at the seamount. The prevalence of immature *M. macropharynx*, particularly for those armorhead with FI <0.26, indicates that infestation at the seamount is probably a continuing process. The presence of *M. macropharynx* in all 775 seamount armorhead with FI of <0.26 also negates the likelihood of a sizable proportion of seamount armorhead becoming uninfested over time.

The maturation rate of *M. macropharynx* on armorhead remains undetermined, but Thoney (1986) has found the oncomiracidia of the morphologically similar *M. sebastis* capable of maturing within 12 days on the gills of black rockfish *Sebastes melanops* (Girard) off northern California. Although armorhead are different hosts, inhabit greater depths, and are geographically distant from black rockfish, the temperature range (12°–17°C) used by Thoney (1986) to determine the maturation time of *M. sebastis* is similar to that found on the summit and upper slope of SE Hancock Seamount. Assuming this rapid maturation also occurs among *M. macropharynx* infecting armorhead, we propose that armorhead with exclusively immature *M. macropharyx* have probably only recently become infested and have seamount residence times that differ little from those of uninfested armorhead. The 0.26 FI value may represent a lower FI limit for potential new recruits, for only 6% of seamount armorhead without mature *M. macropharynx* had FI values <0.26 and the lowest FI value of the epipelagics examined was 0.26. However, an unknown proportion of armorhead with FI ≥0.26 perhaps recruit during the previous year at sufficiently high FI values that these FI values still remain above 0.26 when sampled the following year. Even in this situation, such individuals would be infected with mature *M. macropharynx* by the time they are sampled the following year and therefore not mistaken for new recruits. The presence of *M. macropharynx* probably cannot identify recruits that arrived one or several months before sampling if initial infection occurs soon after recruitment and *M. macropharynx* mature some two weeks thereafter. Hence, our technique can detect only new recruits among the recruit-of-the-year population and is therefore limited to determining whether recruitment is a continuous process.

Of the two condition indices, VFSI shows little promise as an indicator of new recruits, for the VFSI values in epipelagic and seamount individuals broadly overlap, regardless of FI and the presence or absence of mature *M. macropharynx*. Conversely, virtually no overlap in HSI values occurs between epipelagic individuals and any of the seamount armorhead groupings. Preliminary results of sagittal otolith increment enumeration on epipelagic individuals (>27.5 cm FL) and SE Hancock armorhead without mature *M. macropharynx* indicates a common age around 2.5 years (R. Humphreys, unpubl. data). This appears to suggest that those epipelagic individuals examined either remain pelagic or represent "strays" who will eventually or have begun a delayed movement that will result in recruitment to a SE-NHR seamount but a protracted epipelagic phase. The higher mean HSI value of these epipelagics versus seamount armorhead (FI ≥0.26) un-infected by mature *M. macropharynx* suggests that HSI decreases somewhere during the period between movement to the seamounts and time of capture after seamount recruitment. To explain the higher mean HSI of epipelagics and evaluate its efficacy as a recruitment indicator, this forementioned period must be examined in relation to both time and distance.

Of the 27 epipelagic individuals with FLs comparable to seamount populations (>27.5 cm FL) and least distant from the SE-NHR seamounts, 22 were collected around lat. 45°N, long. 155°W; some 2,860 km northeast of the SE-NHR seamounts. Summertime captures of smaller (22–26 cm FL) epipelagics are also frequent from the above general location and indicate an age of some 1.5 years (Boehlert and Sasaki, 1988; R. Humphreys, unpubl. data). Since recruit-of-the-year seamount armorhead are age 2.5 years (R. Humphreys, unpubl. data), these smaller individuals apparently represent the year class which recruit to the SE-NHR seamounts in the following year. Allowing a one-year period (recruitment by the following summer) for individuals of the 1+ epipelagic year-class to move from the open ocean site (45°N 155°W) to the SE-NHR seamounts and also that the total distance traversed is twice the straight-line distance between these sites (assuming this is comparable to results of open-sea tracking of coho salmon *Oncorhynchus kisutch* reported in Ogura and Ishida (1992)), a rough estimate of the average ground speed required is 18 cm/s if currents are disregarded. Based on a length (27.1 cm FL) midway between the average FL of 1+ ($x$ = 24.49 cm FL) and 2+ year-old ($x$ = 29.64 cm FL) epipelagic specimens collected during summers at the open ocean site, individuals would need to swim 0.66 body length/s to arrive at an SE-NHR seamount one year later. This speed is close to the mean sustained cruising speeds (0.2–0.5 body length/second) typical of horizontally migrating fish (Beamish, 1978). Since no evidence exists of gonadal maturation in the epipelagic stage (Humphreys et al., 1989), the major energy demand during seamount migration is likely locomotion, in addition to basal metabolism. It is unknown whether feeding occurs during this migration; however, McKeown (1984) suggests that even if fish species feed during migration, the added energy intake may be negated by the additional energy required for feeding activity. Regardless of feeding, lipid reserves are typically used during migration (McKeown, 1984), and their storage in the liver and muscle makes these prime sites from which energy reserves can be drawn (Woodhead, 1975). As such, the liver is susceptible to net decreases in weight by the end of migration; an example of this occurs among migrating Barents Sea cod *Gadus morhua* (Woodhead, 1975). Evidence of fewer prey contents among higher FI armorhead examined at SE Hancock[3] indicates that recent recruits initially may feed little at the seamounts. This suggests that the liver remains susceptible to continued energy depletion and therefore continued decrease in liver weight. Assuming that liver weight is declining relatively faster than body weight, the HSI will not only decrease by the time of initial recruitment to the seamount but perhaps also during the interval between initial recruitment and sampling. Therefore, an annual or seasonal change in mean HSI among new recruits may be caused by inter- or intra-annual differences experienced by epipelagics in terms of environmental conditions and distance traversed during the seamount migration, along with an unknown time gap between initial recruitment and sampling. Hence, using HSI as a recruitment indicator appears to be inherently more labile and thereby less feasible and reliable than the method based on the absence of mature *M. macropharynx*.

The parasite approach revealed that new recruitment coincided primarily with the late spring and midsummer sampling periods. Somerton and Kikkawa (1992) have analyzed the recruitment patterns of armorhead to SE Hancock, using the modal progression of FI in which separate modes are considered annual cohorts. If a modal influx of high FI fish represents a "recruitment cohort," estimated recruitment was highest in terms of biomass (58 t) and percentage (79%) of the SE Hancock population during August and October 1986, whereas the next highest recruitment (8 t and 21% of the population, respectively) in July and August 1988 was comparatively modest. Interestingly, however, the level of new recruitment, as determined by the percentage of sampled armorhead (FI ≥0.26) un-infected with mature *M. macropharynx*, was highest in June 1985 and very low in October 1986. These results appear contrary to stock assessment based estimates of modest and high proportions of recruit-of-the-year armorhead (FI ≥0.26) in the seamount population during June 1985 and October 1986, respectively (see Fig. 2). These results can be reconciled if we consider that the rate of post-recruitment decline in FI (estimated at 0.00169/month; Somerton and Kikkawa (1992)) does not allow one to decipher between recruits which may have just arrived and those which arrived months prior to sampling. The absence of mature stage *M. macropharynx* appears to be the only criteria examined in this study capable of detecting whether a recruit-of-the-year (FI ≥0.26) is a new arrival to the seamount. Based on this criteria, the level of new recruitment during the months sampled was highest in June, less so in July and August, and very low during October, November, January, and April. These results tend to corroborate evidence of similar seasonal armorhead recruitment at other SE-NHR seamounts (Boehlert and Sasaki, 1988).

Recruits identified via the parasite approach typically have FI values ≥0.26 ($x$ = 0.291). However, a high FI value alone provides no assurance that an individual is a new recruit. The difference in mean FI between epipelagic individuals and new recruits (uninfected with mature *M. macropharynx*) may indicate that FI decreases sometime before epipelagics of recruitment size reach the seamounts. This can be adequately examined only after both groups are further sampled.

## Acknowledgments

We are indebted to the officers and crew of the NOAA ship *Townsend Cromwell*, the RV *Oshoro Maru*, and

# ICHTHYOPLANKTON METHODS FOR ESTIMATING FISH BIOMASS INTRODUCTION AND TERMINOLOGY

*J. R. Hunter and N. C.-H. Lo*

The biomass of a fish stock can be estimated from the abundance of its spawn. This idea, first proposed by Hensen and Apstein (1897), has led to the development of ichthyoplankton methods currently used around the world to estimate biomass, and monitor trends in fish abundance. In recent years, ichthyoplankton based approaches have become more important because of increased demands for fishery-independent information. Five ichthyoplankton based methods for biomass estimation were described in this symposium: annual egg production method (AEPM), annual larval production method (ALPM), daily egg production method (DEPM), daily fecundity reduction method (DFRM), and egg deposition method (EDM). A variety of inexpensive ichthyoplankton indices of fish abundance was also described.

The AEPM (Saville, 1964) was the only ichthyoplankton method for estimating biomass until the 1980's. In the AEPM, biomass is computed from annual estimates of egg production and the potential annual fecundity of females. Eggs collected in plankton tows over the entire spawning season are used to calculate annual egg production. Annual fecundity per unit weight is calculated from the number of advanced yolked oocytes in ovaries of females taken just prior to spawning season.

$$B = P_aA/ER \qquad (1)$$

where B is the biomass for area A, $P_a$ is the annual egg production per unit sea surface area, A is area size, E is the total (annual) fecundity per unit weight of female, and R is the female fraction of the biomass (sex ratio). An important assumption of the AEPM is that potential annual fecundity is determinate, that is, fecundity becomes fixed prior to the beginning of the spawning season. The paper by Picquelle and Megrey on Alaskan pollock, is an example of the AEPM from this symposium.

Determinate fecundity seems to be common in boreal species such as herring and pollock but a common error is to assume that potential annual fecundity is fixed in all fishes. It became apparent in the 1970's and 1980's that the AEPM could not be used for the temperate species such as northern anchovy, queen fish, and tropical tunas because the standing stock of advanced oocytes in the ovary was not equivalent to annual fecundity. For example, female anchovy spawn 10 to 20 times per year, but the number of yolked oocytes in the ovary never exceeded those needed for 1 to 3 spawnings (Hunter and Leong, 1981). Thus, annual fecundity in anchovy is indeterminate and cannot be estimated by counting the standing stock of advanced oocytes in the ovary.

An alternative method, the DEPM, was developed for fishes like northern anchovy that have indeterminate annual fecundity (Lasker, 1985). In the DEPM, biomass estimates are based on daily, rather than annual, fecundity. Daily egg production was calculated from numbers of staged eggs taken in plankton samples. The relationship between daily spawning of eggs and spawning biomass was determined from the fraction of females spawning per day and batch fecundity:

$$B_s = P_0A/(R/W_f)SF \qquad (2)$$

where $B_s$ is the spawning biomass for area A, $P_0$ is the daily egg production at age 0 day per unit sea surface area, $W_f$ is average female weight, S is the fraction of females spawning per day, F is the batch fecundity, and A and R are defined as in equation 1.

Since the publication of the DEPM for northern anchovy (Lasker, 1985), the method has been applied to a variety of fish stocks. These applications provide new perspectives and augment the basic method. In this symposium, Alheit reviews application of the DEPM to clupeoid fishes including Peruvian anchoveta and the Spanish sardine. He surveys the literature, much of which is not generally available, and examines the extent to which the basic parameters in equation 2 vary among stocks of anchovy and sardines. Somerton demonstrates that the DEPM can be used to measure weekly changes in biomass of nehu, a small tropical anchovy, that spawns every other day, and lives less than a year. Shelton, Armstrong, and Roel review the use of the DEPM in South Africa where it has been used to make annual estimates anchovy biomass since 1984. In South Africa, the DEPM has been integrated with an annual acoustic trawl survey for anchovy in a way that yields more precise biomass estimates at a modest increase in cost.

In addition to the DEPM and AEPM, three other biomass estimation procedures are presented in this symposium: the annual larval production method (ALPM); egg deposition method (EDM); and the daily fecundity reduction method (DFRM). All three are based on the assumption of determinate annual fecundity. Heath describes an application of the ALPM to herring and summarizes a large, and not generally available literature. Heath describes how the ALPM was used to monitor the remarkable recovery of European herring stocks. The EDM for Pacific herring described by Schweigert is interesting because plankton samples were not used, instead, divers measured the density and area of spawn on the bottom. Pacific herring spawn in intertidal and subtidal zones where their sticky eggs adhere to algae or the substrate. The spawning grounds are easily found because of the clouds of milt produced during spawning.

The last method of biomass estimation considered in the symposium is the DFRM (Lo et al., 1992). This is a new daily method, that has yet to be formally tested as a management tool. The DFRM is designed to estimate the biomass of fish that spawn more than once per season but have determinate annual fecundity. It does not require measurement of batch fecundity and spawning frequency as do other daily methods. Instead, DFRM uses the daily decline in total fecundities to measure daily population fecundity.

$$B = P_0A/(R/W_f)D = P_0A/K \qquad (3)$$

where B is the biomass for area A, $P_0$ is the daily production of eggs per 10 $m^2$ sea surface, K is daily population fecundity = $(R/W_f)D$, in eggs/body weight/day, $D = d(E \cdot G)/dt$, the daily fecundity per female, E is the total number of advanced oocytes present in the ovary at time t (before spawning, E in equations 1 and 3 are equal), G is the fraction of females that have active ovaries at time t, and R and W are defined as before. If the spawning season is long, the fecundity reduction method requires less ship time than annual method since data from only a portion of the spawning season are needed.

Selection of the optimal ichthyoplankton-based method for biomass estimation is dependent upon a variety of factors including the spawning habits of the parents, whether annual fecundity is determinate or indeterminate, the level of precision desired, costs, and availability of other information. Two symposium papers consider biological issues related to the selection of methods. Zeldis reviews the reproductive biology of three New Zealand fishes: snapper, orange roughy, and hoki, and identifies what he believes to be the optimal ichthyoplankton method for each. Priede and Watson compare estimates of biomass of Atlantic mackerel using the AEPM and DEPM. The calculations for each method use the same ichthyoplankton data but different fecundity data. The results are surprising, because the two methods yielded biomass estimates that differed by only 16%. The estimates may have been similar because oocytes as small as 0.13 mm in diameter were included in the potential annual fecundity of mackerel. If only advanced yolked oocytes were included, the annual fecundity would have been much lower, and, consequently, the biomass based on the AEPM would have been much higher than the one based on the DEPM.

Ichthyoplankton data can be used to monitor trends in relative abundance of marine fishes as well as to estimate their actual biomass. Indices of relative abundance based on ichthyoplankton data are not corrected for variation in population fecundity, and consequently, are less costly and less precise than biomass estimates we have discussed thus far. Although no correction for population fecundity is made, indices may be adjusted for growth and mortality of larvae, or in the simplest case, may be simply the standing stock of larvae or eggs. Regardless of computational details, larva indices are surprisingly sensitive to major changes in stock abundance. For example, Scott et al. show that a larva index based on only 100 plankton samples distributed over 100,000 square miles of ocean can be used to follow major trends in the abundance of bluefin tuna. The possibility that a widespread stock such as bluefin tuna can be monitored with as few as 100 samples is certainly remarkable.

Why do simple ichthyoplankton indices of relative abundance work? Smith, explains that stock size and the area occupied by spawn are correlated, and that the presence and absence of larvae in plankton samples is an efficient measure of spawning area. Larva density, a more costly parameter to estimate precisely, has little importance in determining the size of the spawning area. Smith suggests larva density is of less consequence because most of the determinants of larva density, such rates as predation and starvation, are not related to the size of the spawning stock. In addition, in schooling fish, egg and larva density is probably related to school density which may not vary with biomass.

Many of the methods discussed in the symposium contain assumptions that could bias biomass estimates. Typical assumptions are that current year fecundity, egg mortality, larva mortality, and larva growth do not differ over time or among stocks. Estimates of egg or larva production were imprecise in some cases because the number of samples required for a precise estimate was too expensive to collect. The most precise estimates, in which all parameters are estimated in the same spawning season, have a coefficient of variation of 20 to 30%.

The estimation of the production of eggs ($P_0$) is straightforward and the lack of precision and potential biases are not usually the results of improper sampling or computational approach, but rather, reflect decisions based on costs. Smith makes some suggestions in regard to the frequency of biomass estimates and the precision of such estimates. He concludes that a precise annual estimate can seldom be justified in terms of fishery management and intervals longer than 1 year are more cost effective.

Fecundity estimates continue to be the Achilles heel of ichthyoplankton-based biomass estimation. Unlike estimates of egg or larva production, where procedures are standardized and well understood (Smith and Richardson, 1977), fecundity work may have a number of untested underlying assumptions which may be unsuspected or unspecified. AEPM and the DRFM require that the potential annual fecundity becomes fixed prior to spawning, but this assumption is not valid for all fishes and is seldom tested prior to application of annual methods.

Other typically untested assumptions underlying the annual method are that potential fecundity is equivalent to annual fecundity; females used to estimate potential annual fecundity have not spawned during the current reproductive season and all the oocytes that constitute the potential annual fecundity can be identified in samples. Procedures used to test these assumptions are described by Hunter et al. (1992). In the DEPM one must assume that batch fecundity, usually estimated from numbers of hydrated oocytes in the ovary, is equivalent to the number of eggs actually spawned and fertilized. To our knowledge, this assumption has never been tested. Usually some hydrated oocytes are retained in the lumen of the ovary and are not spawned, indicating that the correspondence between spawned eggs and hydrated oocytes is not exact.

## ACKNOWLEDGMENTS

We thank those who made the symposium possible, especially R. Lavenberg who hosted the meeting. We also thank the symposium participants who provided a stimulating survey of the application of ichthyoplankton methods to biomass estimation, many anonymous reviewers who reviewed the manuscripts, and L. Fuiman, the managing editor of this volume.

## DEFINITIONS

*Annual Egg Production Method (AEPM).*—Spawning biomass estimated from the ratio of the annual production of planktonic eggs to the potential annual fecundity of the stock.

*Annual Fecundity.*—The total number of eggs spawned by a female per year.

*Annual Larval Production Method (ALPM).*—Biomass estimated from the total annual production of larvae, estimated by back-calculating abundance at hatching from abundance at capture length and date, using estimates of growth and mortality rates, and integrated over the spawning area and period.

*Batch Fecundity.*—The number of hydrated oocytes released in one spawning; usually determined by counting the number of hydrated oocytes in the ovary.

*Daily Egg Production Method (DEPM).*—Spawning biomass estimated from the ratio of the daily production of planktonic eggs to the daily fecundity of the spawning population.

*Daily Fecundity.*—The number of eggs spawned per day per gram of fish in the population. In the DEPM it is calculated from the batch fecundity and daily spawning fraction of the stock, while in the DFRM it is calculated from the daily decline in standing stock of advanced oocytes.

*Daily Fecundity Reduction Method (DFRM).*—Biomass (vulnerable to trawls) estimated from the ratio of the daily production of planktonic eggs to the daily reduction in the total fecundity of the stock.

*Determinate Fecundity.*—Annual fecundity is determinate when the potential annual fecundity becomes fixed prior to the onset of spawning. In fishes with determinate fecundity, total fecundity decreases with each spawning because the standing stock of advanced yolked oocytes is not replaced during the spawning season.

*Egg Deposition Method (EDM).*—Spawning biomass estimated from measurement of the numbers of demersal eggs deposited on the bottom by demersally spawning fishes.

*Egg and Larva Indices of Abundance (ELIA).*—Use of the standing stock of eggs or larvae, or the area occupied by spawn, as an index of spawning biomass.

*Indeterminate Annual Fecundity.*—Annual fecundity is indeterminate when the potential annual fecundity of a female is not fixed prior to the onset of spawning and unyolked oocytes continue to be matured and spawned during the spawning season.

*Potential Annual Fecundity.*—Total number of advanced yolked oocytes matured per year, uncorrected for atretic losses. In species with determinate fecundity, potential annual fecundity is usually assumed to be equivalent to the total fecundity prior to the onset of spawning.

*Relative Fecundity.*—Fecundity divided by female weight.

*Total Fecundity.*—The standing stock of advanced yolked oocytes.

## OTHER SUGGESTED NOTATIONS

W: fish weight, $W_f$: female fish weight, $W_m$: male fish weight, L: fish length, $L_f$: female fish length, $L_m$: male fish length, V, $\sigma^2$: variance, $\bar{x}$: sample mean, SD: sample standard deviation, SE: sample standard error, COV: covariance, CV: coefficient of variation, *r*: correlation coefficient, $r^2$: coefficient of determination, T: temperature, df: degrees of freedom, z: instantaneous mortality rate and t: age.

# 1.0 INTRODUCTION

The objective of the Coastal Pelagic Fishes Working Group of PICES (see terms of reference) is to determine the characteristics of the environment, other than fishing, that affect the dynamics of the pelagic fish stocks of the North Pacific. Long term population changes, such as those that may be produced by global climate change, are of particular interest. Consequently, the research and related activities of the Group can be considered to be part of the GLOBEC International program of any PICES country.

The pelagic fishes currently considered by the Working Group are: Pacific herring, (*Clupea pallasi*); sardines (*Sardinops spp*); anchovies (*Engraulis spp*); mackerels (*Scomber spp, and Trachurus spp*); and saury (*Colorabis saira*). The world catch of these pelagic fishes in 1990 was 25 million tons. This catch was 35% of the world catch of marine fishes (Table 1). About 7 million tons of small pelagic fishes are taken annually in the North Pacific (FAO Statistical Areas 61, 67, and 77), with the Japanese sardine accounting for 65% of the total. Only a small portion of the world catch of small pelagic fishes are used directly for human consumption, most of the catch is reduced to fish meal and oil with the meal being an important ingredient of animal feeds. In Japan, where 80-90% of sardine and anchovy catch is used for meal, meal is used to support a rapidly growing fish aquaculture industry. Aquaculture production of fish in Japan, which has tripled between 1970 and 1990, could be seriously affected by a major decline in the Japanese sardine stock.

The general research approach of the Working Group is the comparative method. Our terms of reference state we are "to develop a program for a comparative study of the population dynamics and production of small pelagic fishes in the coastal ecosystem along the western and eastern continental margins of the North Pacific". Comparisons of the dynamics of marine animal populations can be used to test a variety of hypotheses. Comparisons of the same or similar species in different ecosystems can be used to assess effects of population response to different forcing variables (Bakun & Parrish, 1982). Alternatively, comparisons can be made of recruitment success of different species within the same ecosystem to identify specific patterns in the responses to basin-wide environmental change (Hollowed et al., 1987; Koslow, 1984).

**Variation in abundance**

Great variation in population size is characteristic of the major stocks of small pelagic fishes (Csirke, 1988). Considerable variability exists between species and regions. In Japanese waters, the catch of the sardine fluctuates over a two order of magnitude range while anchovy, mackerel, and saury are less variable (Table 2). In California, the same pattern emerges with the sardine population being much more variable than either anchovy or mackerel. Considering the differences in the data between Japan and California, the variability of the three stocks is remarkably similar in the two systems with the coefficient of variation for sardine about twice that for mackerel and with anchovy being roughly a third as variable as sardine. The most striking difference between the two systems is the much greater productivity of the Japanese stocks. On the average, landings of Japanese sardine, anchovy, and mackerel exceed the biomass of the equivalent California stocks.

The processes affecting the recruitment of year classes, and therefore population growth, have been researched for the last 20 years. This body of information on herring, anchovy and sardine, indicates that the recruitment success depends upon the survival of the early life history stages over the first 6 months of life with survivorship in the egg and larval stages being the most variable. Starvation as well as predation may be an important source of mortality during the first few weeks of life but thereafter survivorship is a function of larval growth and their size specific vulnerability to predators. Starvation and growth of early life history stages is fairly well documented but few quantitative estimates of predation exist.

A succession of strong or weak year classes over a decade or more are needed to realize the large and long fluctuations in population biomass, characteristic of many clupeoid populations. This pattern is also found in the physical oceanographic data where decadal periods of ocean climate exist (often called regimes) in which recruitment is either consistently lower or higher than the mean. In support of this argument authors point out correspondences between successions of strong or weak year classes and periods of lower or higher than average sea surface temperatures. How such temperatures affect recruitment remains obscure, however.

Persistent patterns in the success of year classes suggests to others that a positive feedback loop regulating population growth might exist, instead of the density-dependent negative feedback loop usually postulated as a regulatory mechanism. A positive feedback loop is possible in Japanese and California sardine since growth, migration, feeding habitats, and spawning habitats change as their populations grow. In the Japanese sardine energy allocation between growth and reproduction, egg and larval transport from spawning grounds to nursery grounds by the Kuroshio Current, may all be linked to population size. Thus, population response to changes in physical forcing variables may be modulated by internal population processes. Consequently, the long term effect of physical forcing variables on populations should be examined within the context of possible density dependent processes.

Lastly, it is important to recognize that these small pelagic fishes may be more closely linked to long term changes in primary and secondary production than are most other major stocks because they are planktivorous throughout their lives.

# 2.0 DESCRIPTIONS OF STOCKS

## 2.1 Eastern Pacific

### 2.1.1 California Sardine (*Sardinops sagax*)

Three stocks of sardine occur in the north eastern Pacific: a Gulf of California stock (Mexico); a southern Baja California stock (Mexico) [Punta Baja, Mexico to Cabo San Lucas]; and a northern stock (Punta Eugenia, Baja California, Mexico to Monterey, Alta California, USA). The northern stock, immortalized in Steinbeck's book, *Cannery Row*, has a summer feeding migration where fish migrate as far north as British Columbia, Canada.
